My explanation of the case is this: That the child's clavicle was fractured about half an inch internal to its acromial extremity at the time of the mother's accident, and that it united, though in an abnormal position, during the remaining two months of the child's intra-uterine life.

I am, Sir, yours, etc.,

E. R. WILLIAMS, M.R.C.S., etc.

Derby, Jan. 6th, 1883.

VENESECTON.

To the Editor of THE LANCET.

SIR—So firmly am I convinced that, at least in cases of heart disease, venesection is one of the most potent remedies we possess to alleviate pain and protract life, that I venture to believe that both the profession and the public should be deeply grateful to Dr. Broadbent for his paper on the subject. For if bloodletting is ever again recognized at its proper value, it will only be by such lucid and scientific expressions of opinion, proved by and grounded on such a large store of clinical experience, having encouraged the profession to resume a remedy abused for centuries and in disuse for a whole generation, and the public to allow the revival of an operation which became a by-word and a proverb in former days.

Only one word, and that with the greatest diffidence, would I venture to semi-criticism. Dr. Broadbent, it would appear, has never found venesection necessary in aortic valvular disease (p. 5, column ii.). May I refer him to cases recorded in the *Medical Times and Gazette* (Dec. 18th, 1868, p. 707) and in a paper by myself in *THE LANCET* where patients with aortic obstruction seemed to be especially benefited by venesection; and, further, may I express a hope that he will not allow it to be supposed that he at all condemns this treatment in this form of disease. I am the more anxious on the matter because I have seen such good results follow its use. Yet, if Dr. Broadbent maintained that in these patients blood should

not be withdrawn, it is more than probable that his high authority would be quoted against the proceeding in any future analogous case.

I am, Sir, yours truly,

BEDFORD FENWICK.

West-street, Finsbury-circus, E. C., Jan. 13th, 1883.

"PHYSICIANS' PRESCRIPTIONS."

To the Editor of THE LANCET.

SIR—In reference to the course said to be pursued by certain general practitioners in the treatment of their patients, which is the cause of some dissatisfaction just now, will you permit me to mention a case which has just occurred within my own knowledge, and which seems to me to be open to very great objection. The practitioner in this case (by means of a manifold writer) wrote a prescription in duplicate, giving one copy to the patient (a lady), with a request that it should be made up by a particular chemist. The patient of course took it to the chemist, who made up the draught prescribed, but declined to give up the prescription, saying he had received orders from the practitioner that it was not to be given up, but was to be returned to the practitioner. The patient thereupon declined to take the medicine, and wrote to the practitioner informing him of what had occurred, at the same time pointing out that she failed to see why the duplicate handed to her was required by the practitioner, seeing that he had a complete counterpart, and that inasmuch as the prescription was dispensed by a person who did not prescribe it, a patient who took the medicine without having the prescription would be wanting in ordinary prudence. The practitioner, strange to say, has taken no notice whatever of this communication, which omission, although somewhat rude, is perhaps rather an indication of the practitioner's inability to combat the patient's reasoning. It certainly seems to me that when practitioners write prescriptions to be dispensed by chemists, it is absolutely necessary for the patient to possess the prescription, otherwise, in the event of harm following the taking of the medicine, it would probably be difficult, if not impossible, for the patient or his friends to ascertain with accuracy upon whom the blame lay, whether the prescriber or the dispenser. At all events, the chemist, knowing that the patient has no copy of the prescription, is not unlikely to be less cautious in the preparation of the medicine.

I am, Sir, your obedient servant,

W. D. S. C.

Upper Teddington, Jan. 9th, 1883.

THE SALICYLATES IN SCARLET FEVER.

To the Editor of THE LANCET.

SIR—At the present time the following case may prove of interest:—Mrs. D.—'s daughter, aged eight, was taken ill on Wednesday, December 20th, with sickness and feverishness. On Friday I saw her; she had sore-throat, fever, and rash out all over her body, and seemed to be very prostrate. I prescribed eight-grain doses of salicylate combined with a little decoction of logwood, as there was some diarrhoea. She continued her medicine four days, when, the more severe symptoms being quite gone, she was allowed to get up, and in a day or two was running about the house quite well. On Friday, December 29th, she was again taken with sickness and diarrhoea, dry tongue, thirst, etc.; skin very hot and dry. I prescribed bismuth, soda, and aromatic confection. Next day (December 30th) her tongue was red and very dry; throat

very sore; intellect dull; chest, abdomen, back, and front covered with profuse scarlatinal rash; skin burning hot; the diarrhoea and sickness were better. I ordered her eight-grain doses of salicylate every two hours.—Dec. 31st: Morning temperature 102°; tongue moist and red; child has taken her medicine regularly; rash well out; seems much better. To continue the medicine.—Jan. 1st: Temp. 102°; tongue still moist; rash dying away on chest, out on legs; pulse 120; throat sore; glands under jaw and side of neck enlarged; nose sore and discharging. To continue salicylate every three hours.—2nd: Nose discharging; glands not so swollen; child more cheerful; temp. 101.2°; pulse 100.—3rd: Temp. 103°; pulse 100; tongue moist and red; throat sore; rash almost disappeared; glandular swellings about the neck much better; discharge from nose continues.—4th: Refuses food and medicine; temp. 100.4°.—5th: Roof of mouth and tongue dry, covered with black fur; almost unconscious. She died at 9 P.M.

I wonder what the result would have been had I given my little patient the salicylate until at least a week had elapsed in her first attack. Her surroundings were highly insanitary. I have at present in the same house four patients undergoing treatment for scarlatina. They are progressing favorably. Another brother of the deceased is now convalescent from a severe attack, accompanied with anginous symptoms.

I am, Sir, yours faithfully,

JAMES COULDREY.

Scunthorpe, Brigg, Jan. 8th, 1883.

THE DETECTION OF BACILLI OF TUBERCLE IN THE BREATH OF CONSUMPTIVE PATIENTS.

To the Editor of THE LANCET.

SIR—By the following simple method I have succeeded in demonstrating with facility the presence of the bacilli of tubercle in the breath of patients suffering from true tubercular phthisis. For which purpose I allow the patient to breathe, at frequent intervals during the day, through two thin sheets of pyroxyline or gun-cotton, one layer in front of the other, and both of which are placed in the outer compartment of an ordinary "pepper duster" respirator. The cotton when so arranged will act as a double filter—the external layer removing from the in-going air all the suspended particles, such as dust, micro-fungi, starch, etc., which are always more or less present in it, and which it is desirable to exclude; the internal layer retaining only those particles which come from the lungs—viz., micrococci, bacilli, and some epithelial scales. It is, therefore, in the layer which has been next to the mouth of the patient that I seek for the bacilli peculiar to this disease. This I do by converting the pyroxyline into collodion by dissolving the former in a mixture of rectified spirit and ether. By this means the whole of the cotton fibre dissolves, but the organisms which have been emitted from the lungs are unacted on by this menstruum, and remain suspended in it, but not visible to the naked eye.

To render the bacilli manifest, my plan is to pour the thin collodion thus formed on a microscope slide and allow the fluid to run uniformly over the surface of the glass, then immediately to turn the glass on one of its edges, that only the merest film of collodion may remain on the glass. The thinner the film produced the more successful will the experiment be. The film is then to be stained. This may be done by one of the methods now well known to the profession, such as that of

Ehrlich or of Heneage Gibbes. I have had excellent results from the former.

I am, Sir, yours faithfully,
R. CHARNLEY SMITH, M.D., D. Sc.

Ardwick, Jan. 1883.

"CASE OF FEIGNED SKIN DISEASE."

To the Editor of THE LANCET.

SIR—The case of factitious skin disease, put on record by Dr. Colcott Fox, reminds me of one that came under my observation some years ago when I had charge of the dermatological clinique at St. Thomas's. A girl of seventeen, a maid of all work, came before me one winter—that is to say, at a time when hands and arms which are exposed to air and wet are apt to get chapped—with considerable chapping and soreness of all these parts. She professed not to consult me about this however, but about a considerable number of holes in the skin of her forearms, which she said were produced by carrying pails of water and other heavy things up and down stairs. She stated that when thus engaged she would frequently feel something give way in her arm, and that, on looking, she always discovered a newly formed hole. At the moment I was inclined to think that the wounds might really be due to the sudden extension in depth and length of some of the pre-existing chaps, determined by the stretching to which the skin had been subjected. A little examination, however, satisfied me that the holes were of artificial production. They were all of exactly the same character; their direction was horizontal or nearly so; they were oval, or rather egg-shaped, with the pointed end always in the same direction; they were between $\frac{1}{4}$ and $\frac{1}{2}$ inch in length; their edges were smooth and vertical, and they looked as though they had been made with a punch; there was no surrounding thickening or inflammation, and their floor was formed of the healthy subcutaneous connective tissue. I concluded she had snipped out pieces of the skin with scissors. I explained my views to my class, out of the girl's hearing; and one of them left the room and presently returned with two or three wounds in his arm, which were the exact counterparts of the girl's. He had made them with scissors; and added that no pain attended their production. I said nothing to the girl on her first visit; but on the second, charged her with deceit, and threatened to inform her mistress. I need scarcely say I did not see her again.

I remain, Sir, yours truly,
J. S. BRISTOWE.

Old Burlington-street, Jan. 5th, 1883.

SUCCESSFUL GASTROTOMY IN JAPAN.

To the Editor of THE LANCET.

SIR—I found the following remarkable account of a unique and scarcely credible surgical feat in a copy of the *Hongkong Overland China Mail* sent to me the other day. Considering the great interest and importance of the operation of gastrotomy, and the prominence it has recently assumed, I thought it might not be uninteresting to your readers to bring before them this tale of operative triumph from the Land of the Rising Sun. Albeit there is a smack of the fabulous about it, there is no reason to deny its authenticity.

I am, Sir, yours faithfully,
D. BEATTIE BAIN, M.B., C.M.

Tay-street, Dundee, November 27th, 1882.

"The *Choya Shimibun* tells an extraordinary story of skill and courage on the part of a Japanese

doctor. It runs to the effect that one morning, as a certain man named Ito was cleaning his teeth, by some means or other he let his tooth-brush slip down his throat. Medical assistance was at once procured, and the unfortunate man, who was suffering the acutest agony, drenched with purgatives, but all to no avail. It was not till the fifth day that a certain Dr. Hashimoto, principal of the highest medical college in Tokio, was called in. Dr. Hashimoto said there was just one chance to save the man, and as the case was desperate it might as well be tried, for the patient would certainly die, and that almost immediately, if nothing was done. The friends consenting, chloroform was administered and two deep incisions were made cross-wise in the man's body. The stomach being laid bare, it was discovered that the tooth-brush was deeply embedded in it, and that, one edge of the handle being sharp, it had worked its way half through. The thing was speedily extracted, and the two wounds, inner and outer, deftly sewn up by the operator, who is said to have won immense renown by the success which crowned his efforts. The *Choya Shimibun* adds that the man to whom the accident occurred is now in a fair way of recovery."

GAS FIRES.

To the Editor of THE LANCET.

SIR—In my practice as an architect I have from time to time recommended the use of open gas fires, not only from their convenience and cleanliness, but because, when more universal, their use will at least assist in abating the intolerable smoke nuisance arising from the ordinary open grate. I have three or four open gas fires in my own house. I am now informed, upon high medical authority, that these fires are most harmful. In a case which has recently come under my notice the gas fire (one of Verity's) has been instantly ordered out of the room, and in the same grate is now burning a coal fire.

The question I would ask is as follows:—Given a good grate and free updraught, is the heat radiated from burning coal harmless, and the heat radiated from asbestos, warmed by an atmospheric burner, dangerous? I write as a layman, not understanding these things, but feeling that a qualified opinion in the matter must be of great value, and I know not how to obtain this except through your columns.

I am, Sir, yours obediently,
SOMERS CLARKE.

Dean's-yard, S.W., Dec. 1st, 1882.

* * Provided that there are efficient arrangements for the escape of the products of combustion, there is no objection on the score of health to the use of gas fires. We have known instances of these fires being fixed in ordinary grates, and in order to increase the amount of heat given off from them the register has been closed. This, of course, is inadmissible.—ED. L.

CASE OF FREQUENT TAPPING IN ASCITES.

To the Editor of THE LANCET.

SIR—B. S—, aged forty-two years (formerly a hospital nurse), was anxious that her case should be noticed in your valuable journal, and as it may interest some of your readers, I am glad to comply with her request. I may briefly state that the patient had been under treatment for many years at various times for congestion of the liver and

stomach, and was eventually brought to death's door from an attack of violent hæmatemesis, from which she rallied slowly. The dropy first showed itself during her recovery. Having diagnosed the case to be one of cirrhosis of the liver, I tapped her early, and removed about a gallon and a half of fluid on Jan. 8th, 1881. Between this date and Aug. 27th, 1882, I tapped her no less than thirty-nine times, and removed 110 gallons of fluid, the patient finally sinking from exhaustion on Sept. 7th. The treatment was merely palliative, the usual remedies for dropy not suiting her. I used a cannula of small calibre, with india-rubber tubing attached, the process of tapping generally lasting an hour; and since it was so well borne, I was enabled to visit other patients in the interim. None of the directions mentioned in the text-books as to the use of compress and bandage were complied with, and the patient lay on her back or side, as she felt disposed. No post-mortem was made, as the nature of the case was evident.

I am, Sir, yours, etc.,

R. H. PATERSON, M.R.C.S.

Edinburgh, Dec. 1882.

News Items, Medical Facts, &c.

IMPROMPTU ON THE VACCINE INOCULATION.

(From the Morning Herald, Friday, June 8th, 1863.)

When Io's charms had amorous Jove estrang'd,
Saturnia to a cow her rival chang'd;
Then Venus cry'd, "The beauty you deface
Shall shield the beauties of a future race;
Her favoured offspring shall from earth remove
The direst foe of beauty! life! and love!"

DOG BITES.—An absurd superstition prevails that the bites of all dogs should be either cut out or canterized, and the poor animals destroyed. It is not necessary to adopt either of these serious courses provided the dog is healthy. In fact they are simply ridiculous, and are calculated to produce groundless fear in the person bitten. Of course in severe cases erysipelas may supervene, but with ordinary care, the wound being cleansed by a disinfecting lotion, no serious consequences will follow. In all cases, however, a doctor should be consulted.

IMITATION BUTTERS.—Of these there are several kinds. *Butterine* is made by a respectable firm and of sound materials, and is a cheap and wholesome substitute for butter when this is dear. It is made, according to one receipt, by melting beef suet in warm water with carbonate of potash; then pressing out the oleo-margarine from the stearine, mixing the former with the soluble matter from cows' udders, a little annatto, and a due proportion of milk, and then churning. *Bosh* is made by a direct admixture of various fats with (often very inferior) butter.

THE CONSUMPTION OF TOBACCO.—Those who take part in the perennial crusade against tobacco, and all who disapprove of its excessive use, will be glad to learn that the consumption of tobacco is as small in England as in any other civilized country. From some statistics on the subject which have been published by a French journal, *Les Mondes*, it appears that in Russia, France, and England the consumption amounts to 1 lb. per inhabitant. In Italy it is rather higher, 1½ lb. Austria comes next with 2-2½ lb. In the United States and Germany the consumption amounts to 3 lb., in Belgium to 4-4½ lb., while Holland has the privilege

of heading the list with a consumption per inhabitant of more than 5½ lb.

A CONTRIVANCE TO PREVENT "BALLING" OF HORSES' FEET.—The *Live Stock Journal* gives an account of a contrivance adopted by Col. Anstruther Thompson, of the Fife Hounds, for the protection of horses' feet from snow, from which medical men may take a hint—many of them finding it difficult to get through their work owing to the delay caused by the insecure footing afforded their horses. Col. Thompson takes a sheet of gutta-percha about a quarter of an inch thick, cuts out a set of plates a little larger than the hoof inside the shoe, softens them in hot water, and moulds them inside the shoe over the frog, so that a face of gutta-percha touches the ice and snow, and "balling" with snow is impossible. These plates remain until the end of the bad weather.

MUSHROOM CATSUP.—A microscopical examination of several samples of mushroom catsup has recently been made by a well-known fungologist, Mr. Worthington G. Smith, and has brought to light several details of its composition that must be highly pleasing to lovers of this condiment. Of four samples manufactured in London, in one he found only matter which looked like mashed-up toast and salt; in another decayed fish, mildew, and broken twigs; in a third, fungus spawn, mildew spores, crushed walnut-husks, and vibriones, large black spores evidently belonging to the genus *coprinus*, and brown ones recognizable as those of the horse-mushroom. Genuine mushroom catsup should exhibit basidia, cystidia, and spores of the true mushroom, salt crystals, and occasionally a pollen grain or fragment of pappus, but nothing more.

THE EFFECT OF THE ELECTRIC LIGHT ON HEALTH.—The above question was lately discussed at a meeting of the Hygienic Society of Hamburg, and Dr. Krüss explained his views on the subject at some length. He referred to the influence of the electric light on the human eyesight, and expressed his opinion that it produces no evil effects, the light having a violet tinge under most circumstances. He referred to the somewhat exaggerated expectations which had been formed as to the distance at which the light was visible at sea; but, on the whole, he considered that the safety of human life at sea had been increased by the use of the electric light in lighthouses. The electric light being free from the disadvantages incidental to the combustion of gas in the consumption of oxygen and the production of carbonic acid, he considered its development as being a hygienic measure of relative importance.

OBITUARY.—Dr. Thomas Hume was born in Dublin, and died at Hanwell, October 21st, 1850, aged eighty-one. He was the constant friend and medical attendant of the great Duke of Wellington, and, as physician to the forces, followed the duke through all his campaigns. A good story is told of him. Going into a newspaper office in the Strand, he laid on the counter an advertisement of the death of a friend, with the usual fee of five shillings, when the clerk, reading it, said curtly, "Seven-and-six." The doctor replied that he had never paid more than five shillings for these simple announcements, to which the pert young fellow said, "Simple announcements! he died 'universally regretted!' Seven-and-six." In placing the additional half-crown down, the doctor said, "Well, young man, that is an additional expense which your executors will not have to pay." He was the last descendant of the celebrated mathematician, Dr. John Wallis.

THE INFLUENCE OF SULPHUROUS ACID IN ARRESTING PHTHISIS.—Herr Kircher, a pupil of Liebig, has been during forty-four years director of an ultramarine factory, in which a special process of manufacture is employed which involves the formation of sulphurous acid by the burning of sulphur. He maintains (according to the *Gesundheit*) that none of his workpeople have ever suffered from consumption, typhus, cholera, or any disorder which is produced by bacteria. He recommends the following treatment in the case of tuberculous patients. They should be brought into a room in which small quantities of sulphur (one to two drachms) are burnt every hour over a spirit lamp or on a stove. At first coughing of a more or less aggravated character takes place, and after eight or twelve days the bacteria gradually disappear and cease to irritate the lung-tissue. To complete the cure, the patients should be brought into rooms which contain some aromatic vapors.

NOTES IN SEWER AIR.—In a paper read recently by Dr. W. A. Hollis, at the Brighton and Hove Natural History Society, on "Notes from a Sunbeam under the Microscope," amongst much that is interesting, the following passage occurs: "Show me a town with a long intercepting outfall, closed by the tide for twelve hours in every twenty-four, and *pro tempore* converted into a bubbling cesspit, and I shall show you a place where, in spite of man-holes and street-gratings, in spite of ventilating-shafts and dip-traps, sewer-gas will occasionally force its way backwards into courts and into houses, to the enfeeblement, and it may be to the death, of the inhabitants. All tidal outfalls ought to be abolished. These regurgitant aerial currents laden with motes, ever present in sewer-gas, will be intensified whenever the barometer or the thermometer is low. Then will they mingle their baleful products with the air we breathe, to the injury of our health, the damage of our reputation, and the curtailment of our prosperity."

FORTY INCHES OF BOWEL PASSED PER RECTUM, WITH RECOVERY.—At a recent meeting of the Baltimore Academy of Medicine, Dr. Christopher Johnston exhibited a specimen of forty inches of intestine passed by a lady in Charles County, Md., per rectum, which, together with notes of the case, had been sent to him by Dr. W. N. Saunders, under whose care it occurred. The patient, who was thirty-two years old, married, and had one child, had always been delicate, and subject to indigestion, constipation, and colic pains. The attack during which the present specimen was passed began with acute epigastric pain, followed in three days by stercoraceous vomiting, which produced slight relief of the pain. For nine days previous to the vomiting there had been no action from the bowels, and a circumscribed hardness could be easily felt through the abdominal parietes. After the vomiting, which lasted three or four days, the sphacelated bowel, together with some of the omentum, was passed. Part of the specimen retained its tubular shape, and contained feces; another part passed mixed with feces. The patient then began to improve, although still troubled with occasional pain in the bowels, especially in connection with her evacuations. The treatment pursued was cathartics, enemata, inflation, anodynes, etc. The specimen was supposed to be a portion of the ileum.

CROTON OIL.—The result of the researches of M. L. Julliard has been published in the *Union Pharmaceutique*. The question which M. Julliard set himself to decide was whether pure croton oil was or was not soluble in alcohol, the account given by different authors concerning its solubility being discordant. It is, however, very generally

known that by repeatedly treating croton oil with alcohol, its purgative, acid, rubefacient, and general active properties are greatly weakened, if not wholly destroyed. According to M. Desnoix, 95 per cent. alcohol will dissolve two-thirds of the oil, but M. Julliard's experiments reversed these figures. The *Dictionary of Adulterations* of Chevallier and Baudrimon states that croton oil is entirely soluble in alcohol at 40°, while the Dublin Pharmacopoeia denies it altogether. The differences in the accounts given in various text-books of the solubility of this oil in alcohol may be attributed to the fact that the greater portion of the croton oil used has, by the time it reaches the consumer, been pretty well adulterated with castor or some other oil, the presence of which it is difficult to ascertain with any degree of certainty. Some authors attribute the active properties of croton oil to the presence of resin; others, among whom may be mentioned Pellatier and Ginbourt, ascribe them to crotonic acid, while Dublanc absolutely denies the existence of this acid, and Schlippe puts them down to a peculiar principle which he calls crotonal, so that none of the authorities are really agreed as to what is the really active principle of this oil.

INSUFFICIENT WATER-DRINKING.—Dr. Maas, Professor of Surgery at Freiburg (Baden), has recently published the results of his investigations on the above subject which he made with special reference to sunstroke. An artificial perspiration (or, rather, absorption of the water in the system) was effected in the case of the animals subjected to these experiments with the result of the temperature of their bodies being considerably reduced. When liberated, the animals drank abundantly of the liquids placed before them, but usually died in the course of the same or the following day, the loss of heat having induced weakness and death. The pressure of the blood becomes diminished under such circumstances, and the processes of nourishment and digestion show reduced activity. In the case of a powerful dog of medium size, the pressure of the blood fell during the four hours' experiment from 128 to 59. Upon dissection it was found that several of the organs were extremely dry and distended. He states the fact that in cases of death from sunstroke, appearances have been noticed upon post-mortem examination, corresponding more or less with those observed in the experiments upon animals. In such cases alcoholic liquors, such as brandy, beer, etc., are not recommended, the first and most urgent requirement being the replacing of the water which is wanting. It is remarked that this is best done by lukewarm or warm water, as they are most rapidly absorbed. The addition of wine, coffee, or tea is also disapproved by Dr. Maas, who recommends the addition of a little acetic acid or citric acid, as the transition into the blood of water impregnated with acid is quicker than it otherwise would be. The importance of a daily provision for the maintenance of the due quantity of fluid in the system is commented upon in the remarks of the *Gesundheit* upon the theory propounded by Dr. Maas, and it is suggested that a pint of water should be drunk every morning on rising, and a similar quantity before retiring to rest; while one to one and three-quarters of a pint of water should be taken after each important meal. The neglect of precautions for keeping up the supply of water causes, it is said, diminution of the quantity of blood, lowering of temperature, and loss of strength, thus indicating premature death.

ABSTRACT OF A

Lecture

ON

THE OCCURRENCE OF THE MITRAL DIRECT OR PRESYSTOLIC MURMUR WITHOUT MITRAL LESIONS.

By AUSTIN FLINT, M.D.,

Professor of the Principles and Practice of Medicine and of Clinical Medicine in the Bellevue Hospital Medical College.

THE case at the hospital which was recently brought before you, in which were four heart murmurs referable to the left side of the heart, and associated therewith paroxysms of angina pectoris, is doubtless fresh in your recollection. The patient, as you will remember, died suddenly in a paroxysm of angina, and the case furnished an occasion for considering that affection. I have now the heart before me. You see at once that it is considerably enlarged; the weight is 17½ oz. The enlargement is chiefly of the left ventricle. The ventricular cavity is much dilated, the dilatation evidently predominating over the hypertrophy. Directing attention to the aortic orifice, you perceive that the sigmoid walls are thickened and contracted. There had been, evidently, considerable regurgitation, and this stands in a special causative relation to the hypertrophy and dilatation of the left ventricle. The inner surface of the aorta above the aortic orifice is thickened and velvety. The openings of the coronary arteries are much contracted, and this, taken in connection with the insufficiency of the aortic valves, must have had for a consequence a deficient supply of arterial blood to the muscular structure of the heart. In my remarks on angina pectoris I stated that, as it seems to me, the most rational view as regards the pathological condition with which paroxysms of angina are connected is to attribute them to ischemia of the heart. That condition must have existed in this case, and the appearances therefore go to sustain the ischemic theory.

Let us now direct our attention to the mitral orifice. Here there is not the slightest appearance of lesion. The mitral curtains are perfectly normal. Moreover, before the ventricular cavity was laid open, the water test showed competency of the

mitral valves. The specimen has for me great interest in connection with these facts. The patient, in this case, had undoubtedly both a mitral systolic and a mitral presystolic murmur. I found these murmurs present on repeated examinations, the presystolic murmur varying at different times in its loudness, but never absent. The presence of both murmurs was verified by many others. The case served to illustrate their differential characters to clinical classes. It so happened that Mr. Gould, of London, visited the ward on the day before the sudden death of the patient, and he listened to the heart as presenting a good example of the presystolic murmur. This murmur had, in this case well marked, its usual distinctive features—namely, a rough vibrating quality, resembling, in this respect, the sound produced by throwing the lips into vibration with the expired breath. From this peculiar quality I have been accustomed to distinguish the murmur as a blubbery sound. Now, the question arises, How could this murmur have been produced without any mitral lesion? I find no difficulty in answering this question, and I ask your attention now especially to the explanation of the fact that a mitral presystolic murmur may occur without any mitral lesion.

In 1862, in an article on "Cardiac Murmurs," published in the July number of the *American Journal of the Medical Sciences*, I reported cases illustrative of the facts just stated. I am not aware of any case having been reported prior to that date in illustration of this fact, nor subsequently by any other observer. The fact was stated in the first edition of my work on the "Practice of Medicine," published in 1866, as well as in the subsequent editions. I have met with several additional instances within the last twenty years.

As preparatory for the explanation, the mode of production of the murmur, when it represents mitral lesions, is to be borne in mind. Referring to the characteristic blubbery murmur, I believe it to be produced by vibration of the mitral curtains. The mechanism is the same as in the imitation of the murmur by the vibration of the lips with the current of air in expiration. In thus imitating the murmur, note with how feeble a current of air a loud blubbery sound is produced by the vibration of the lips. This at once disposes of the statement which has been made that the current of blood produced by the auricular contraction is too feeble to give rise to so loud a murmur as is the mitral presystolic in many cases. Accepting the

mode of production of the murmur as just stated, it follows that when the murmur is organic the mitral curtains must be flexible, that is, capable of vibrating. Whenever the murmur is due to lesions, the flexibility of the curtains is to be inferred, and generally it is a fair inference that there is contraction of the mitral orifice in consequence of adhesions at their sides, being what is known as the button-hole aperture. If the curtains be rigid and notably contracted, the characteristic murmur is not present; either there is no appreciable murmur, or it is a blowing murmur. It may be wanting, and hence absence of the mitral presystolic murmur is not positive proof that mitral obstructive lesions do not exist.

Now for the explanation of the mitral presystolic murmur without mitral lesions. In all the instances which have come under my observation there have been aortic lesions permitting regurgitation, as in the heart which is now before me. With regard to this specimen, consider the physical conditions in life at the instant when the auricular contractions took place. The left ventricle was filled with blood from the current passing from the auricle to the ventricle through an unobstructed orifice by gravitation, and, in addition, the regurgitant current from the aorta. As a consequence, the mitral curtains were floated away from the ventricular walls, and were not only approximated but in absolute contact. Recollect the physiological experiment by which it is shown that the mitral valves may be completely closed by injecting a liquid into the left ventricle through the mitral orifice. These conditions existing, the auricle contracts and forces an additional quantity of blood into the ventricle. This mitral direct current passes between the valvular curtains which are in apposition, and throws them into vibration precisely as the lips are made to vibrate with the breath. If I have made myself clearly understood, you will admit, as it seems to me, that the explanation is rational and adequate. Looking no further than the mitral orifice, the murmur is inorganic or functional, but, occurring without mitral lesions, it is an effect of aortic lesions allowing free regurgitation. I have as yet met no instance in which aortic regurgitant lesions did not coexist. Under these circumstances the presystolic murmur is apt to be variable in its intensity at different times, and it may not be always present—that is, it is liable to come and go according to variations in the physical conditions involved in the mode of its production.

To this statement concerning the variableness and intermittency of the mitral presystolic murmur without mitral lesions, I will add a fact, which I do not recollect to have seen stated by any author except myself, relating to the murmur when it represents mitral obstructive lesions. The fact is this, the murmur, in the progress of the cardiac affection, may become variable and intermittent. The fulness and cessation of the murmur, under these circumstances, are not of good omen, but quite the reverse. They denote feebleness of the auricular contractions from dilatation. The coexisting signs and symptoms will be found to sustain this view. Do not, therefore, fall into the error of giving to a patient, or to friends, false encouragement when, connected with mitral lesions, a murmur which has been loud and constant becomes feeble or ceases to be heard.

In the case which furnished the specimen before us there was also a mitral systolic murmur, and, as has been stated, the water test did not give evidence of insufficiency of the mitral valves. How is this fact to be explained? I do not propose to discuss the various explanations of the production of a mitral systolic murmur without mitral lesions.

Suffice it to say that in this case, taking into view the considerable dilatation of the left ventricle, it seems to me probable that, although the ventricle held water when filled from an opening made through the apex, the ventricular contraction in life occasioned some regurgitation. A regurgitant stream, be it never so small, may give rise to a murmur. I submit this explanation without undertaking at this time to account for the apparent incongruity that the mitral valves may admit of some regurgitation during life, and yet be found competent after death.

Clinical Lecture

ON A CASE

OF TROPICAL ABSCESS OF THE LIVER.

Delivered at the Middlesex Hospital.

By J. KINGSTON FOWLER, B.A., M.B.,

Assistant-Physician and Pathologist to the Hospital, and Assistant-Physician to the Brompton Hospital for Consumption.

GENTLEMEN—The patient whose case will form the subject of my remarks, and whom I shall presently show to you, is a man aged twenty-seven, well built, of good muscular development, and by occupation a navy. He was admitted into the hospital on April 11th, 1882, complaining of cough and pain in the right side; he came under my care about a week later. He gave the following account of himself: He had enjoyed good health up to four years ago, when he was laid up for six weeks with an attack of acute rheumatism affecting the ankle, knee, and hip-joints; since then, with the exception of an occasional cold and cough, he has remained well. He stated distinctly on several occasions, in reply to questions, that he had never been out of England; and it was not until we had been obliged to take the first important step in treatment that we discovered that he had enlisted in a cavalry regiment in 1869, and in February, 1870, had been sent to India. For the first year he was stationed at Bangalore, in the Madras Presidency, and whilst there was quite well. The regiment was then moved to Secunderabad, and remained there five years, during which time he was twice in hospital: in 1873 for six weeks with Indian fever, the principal symptoms being fever, vertigo, weakness, and loss of weight; in 1874 for ten weeks with fever and pain in the right shoulder and hypochondrium. He remembers that on one occasion during this attack his temperature rose to 106° F., but he had no diarrhoea, dysentery, or jaundice. There can, I think, be little doubt that this second attack was one of acute hepatitis. After recovery he returned to duty, and remained two years longer in India. He left the army in 1877, and has since worked as a navvy.

We now come to his present illness. On April 2nd, whilst working on a "night shift" in a tunnel, he felt sick and giddy and shivered. He went to bed, but though wrapped in blankets the shivering continued more or less during the whole of the following week. On April 6th sweating first occurred; it was continuous, but most profuse during sleep. On the 9th he complained of pain of a sharp character, localized in the right loin and epigastrium. He vomited several times, and suffered also from cough, with expectoration of frothy, but not rusty mucus. There was no pain in the right shoulder, jaundice or diarrhoea. On admission, the skin was of a sallow tint, and he

was perspiring; the tongue was coated and brown in the centre. Temperature 101° F; pulse 84, soft and compressible. There was troublesome cough; the expectoration frothy and of a slightly yellow color. On physical examination no adventitious sounds were heard in the lungs. The cardiac apex was in the normal position, and the sounds normal. The liver dulness was not increased, and the splenic dulness was normal. The urine deposited lithates on standing, and was free from sugar and albumen. On the following morning the temperature was 103° F. He had passed a restless night, and had perspired profusely. On the 14th it was noted that the breath sounds at the right base were weak, and accompanied on expiration by sibilant rhonchi. These sounds gave place soon after to fine crepitant râles. The bowels were freely opened after taking five grains of calomel, the motion being of a dark-brown color. For the next few days he remained in much the same condition. The temperature fluctuated between 99° F. in the morning and 103·4° in the evening. The sweating was continuous and profuse, especially during sleep. The cough was troublesome and expectoration copious, but it was never rusty. At the right base, posteriorly, there was diminished vocal fremitus; the percussion note was flat; the breath sounds feeble, and some fine crepitant râles were heard. The cardiac apex was not displaced. The pulse rose on the 19th to 120, and was soft and dicrotic, and he was evidently losing strength rapidly. I was struck when I first saw this patient with profuse perspiration, and remarked that the case reminded me of two which I had seen at Addenbrooke's Hospital, Cambridge, which proved to be cases of hepatic abscess. I have since then been strongly impressed with the fact that *when obscure disease—e.g., pleurisy with doubtful pneumonia—at the base of the right lung is associated with profuse sweating, the formation of an hepatic abscess should be suspected.* On April 21st I carefully examined the liver, with the following result: the lower ribs on the right side were slightly bulged; there was slight fulness and increased resistance in the epigastrium and some tenderness on pressure there; the liver dulness commenced at the fifth rib, and measured six inches in the right mammary line, and five inches and a half in the mid-sternal line; there was no hydatid thrill or fremitus; the right rectus abdominis was tense. Dr. Cayley kindly saw the case in consultation with me, and agreed that it was quite justifiable to make an exploratory puncture into the liver. I therefore thrust an aspirator needle, one-eighth of an inch in diameter, into the liver one inch below and the same distance to the right of the tip of the ensiform cartilage, and with the point at a depth of about two inches pus began to flow through the tube. After about an ounce had escaped the tube became blocked, and as the object of the puncture had been attained I withdrew the needle. The pus was thick, curdy, blood-stained, and contained solid flakes; on microscopical examination no hooklets of echinococci were found. On the following morning, at my request, Mr. Andrew Clark plunged a large trocar into the same spot and drew off twelve ounces of pus having the same characters as that previously obtained. The cannula was allowed to remain in and a large poultice applied over it, some carbolic tow being placed immediately over the orifice. At 2 p.m. on the same day the temperature had fallen to 99°; but it rose again in the evening to 102·8°. On the 24th, he was ordered sulphate of atropia, 1-100th grain in pill every night, with the view of checking the sweating; this it did very effectually for a time. For the next few days the temperature ranged

lower than before the operation; there was a free discharge of healthy pus from the cannula; the abscess sac was washed out thrice daily with a 2 per cent. solution of carbolic acid; and he took three-grain doses of quinine three times a day. On the 26th the cannula was removed and a drainage-tube inserted. On the 29th the drainage-tube accidentally slipped out of its place; and could not be re-inserted into the abscess sac; I found it lying in the sinus, and removed it altogether. The discharge still continued, but was not free. The range of temperature was between 99° in the morning and 103° in the evening. For the next fortnight he continued in much the same condition; the temperature maintained the hectic type; the sweating, though less profuse, was still continuous, and the discharge was not free. The lower margin of the liver could now be felt two inches below the ensiform cartilage, and it was clear that pus had again accumulated and filled the abscess sac. On May 14th I determined to tap the liver again, and plunged in a trocar, having a diameter of three-eighths of an inch, just above, and internal to, the first opening. Pus flowed freely through the cannula, and in all rather more than twenty ounces were withdrawn. It had not altered in character since the first tapping. Towards the end of the operation, when it was thought that the greater part of the pus had been evacuated, he began to retch, probably as a result of the ether he had inhaled, and the compression of the liver between the abdominal muscles and the diaphragm forced out a large quantity of pus. Coughing and retching are useful, though possibly rather dangerous, aids to the emptying of an hepatic abscess. The cannula was now withdrawn, and a laminaria tent inserted in order to dilate the opening. This was removed in four hours, and replaced by a drainage-tube. The effects of the second tapping were extremely favorable. The lower edge of the liver receded an inch and a half. The temperature fell to the normal at once, and for nearly three weeks did not rise above 99°. The tongue cleaned, the appetite improved rapidly, the sweating almost ceased, and there was a moderate discharge of healthy pus. His progress towards convalescence, however, received a sudden check; for during the night of June 3rd, whilst the dressings were being changed, the tube was accidentally withdrawn, and was not at once replaced. This unfortunate occurrence was immediately followed by a severe rigor, in which the temperature rose to 103·4°. He sweated profusely, the tongue quickly became brown and dry, and when I saw him in the afternoon his condition appeared extremely critical. A long laminaria bougie was inserted and allowed to remain in three hours, and he was ordered quinine in fifteen-grain doses three times a day. When the tent was withdrawn the drainage-tube was replaced without difficulty, and, the discharge being re-established, all the bad symptoms at once disappeared. On the following day he was quite as well as before, and the large doses of quinine were discontinued. Since then he has made steady progress towards recovery. On June 28th, the discharge having almost ceased, I withdrew the tube, as the sinus was evidently granulating upwards, and the sac appeared to have become obliterated. It is quite possible that the tube might have been safely dispensed with earlier, but, warned by our previous experience, I was anxious not to close the wound before it appeared certain that the abscess had healed. The physical signs noted at the right base gradually cleared up, and the lung symptoms ceased to give trouble after the first tapping. The edge of the liver cannot now be felt beneath the ribs, and the sinuses have completely closed. The diet at first was liquid, and suited to his feverish

state, but as soon as the appetite returned I allowed him as liberal a diet as he desired.

I should like now to direct your attention to some of the chief points of interest in this case. First, as to its nature. It was soon clear that this was not an ordinary case of pleurisy with effusion or an empyema depressing the liver. The normal position of the cardiac apex alone negatived such an hypothesis. The physical signs, so far as the lung alone was concerned, were consistent with a rare form of inflammation, of which some of you have lately seen an example, in which the bronchi, even the primary branches in the affected area, are filled with fibrinous coagula. This condition has been named "massive pneumonia." This would not, however, have accounted for the profuse sweating, a symptom almost constantly met with in abscess of the liver, and which formed one of the most marked features in this case. I think there can be little doubt that we have been dealing with a tropical abscess of the liver, the result of the attack of hepatitis, from which the patient suffered whilst stationed at Secunderabad in 1874. It is quite possible that a small collection of pus may have remained encysted in the liver during the eight years which have since elapsed, and during which our patient has enjoyed good health. From some cause, which we can only guess at, possibly a strain whilst at work, the sac may have ruptured and set up an acute inflammation in its neighborhood. Or it may be that without actual pus having been encysted there were residues of the old inflammation lying quiescent in the liver, and around these suppuration occurred. Sir James Paget has shown how this may take place in other parts of the body, and Dr. Murchison suggested this explanation of those cases of hepatic abscess occasionally met with in persons long resident in this country who have suffered from hepatitis in the tropics.

Another point of interest is the prompt relief to all the symptoms which followed on the evacuation of the pus, and continued so long as the discharge was free, notwithstanding that a large portion of the liver must have been destroyed. In some other cases of the same kind which I have seen recovery has taken place with equal rapidity when once a free exit has been given to the pus.

The most common causes of hepatic abscess as it occurs in this country are either pyæmia or suppurative of an hydatid cyst. We may exclude the former, because the abscess was large and single, whereas pyæmic abscesses are usually small and numerous, and almost invariably have a fatal termination. That we had not to deal with a suppurating hydatid cyst is, I think, clear from the fact that frequent careful examination of the pus failed to detect any hooklets of echinococci. You will have noticed that the patient is stated never to have had dysentery.

The connection between dysentery and tropical abscess is a point which has been much discussed, and is still undecided. Sir Joseph Fayrer, in common with many other distinguished Indian pathologists, holds the opinion that "the two affections are independent though often coexistent and due to the same climatic causes; that hepatic abscess does occasionally result secondarily by absorption from the ulcerated bowel, and is then of the nature of pyæmic suppuration, in which case it is apt to be multiple and more serious in character than ordinary tropical abscess." It is, I believe, now generally recommended that the single large abscess, from whatever cause arising, should be opened as early as possible; but considerable difference of opinion still exists as to the best method of operating, whether by incision or with a trocar. If the abscess be distinctly point-

ing, it may be opened by incision, but even then I should prefer to use a trocar, and if it is at all deeply seated, there are decided advantages in adopting that course—viz.:

1. The risk from hæmorrhage is much less; for when the liver is incised there is often a violent gush of blood. This, it is true, soon ceases; but these patients are usually not in a condition to bear a loss of blood which a distinguished surgeon, Mr. Lister, describes as "alarming."

2. There is less danger from septic absorption along the track of the wound, as the pus flows through a cannula or drainage-tube.

3. As a trocar of any diameter may be used, the opening into the sac may be of any size that is considered desirable. For an exploratory puncture I prefer one having a diameter of one-eighth of an inch; but if there is certain evidence of the presence of pus, it is very important to employ an instrument of at least three-eighths of an inch or half an inch in diameter. If a smaller one be used, it is liable to get blocked by the solid shreds of liver tissue which these abscesses so frequently contain.

The site to be chosen for the puncture must be determined in each case by the physical signs, but it is better, if possible, to avoid going between the ribs or cartilages, as the trocar must then pierce the diaphragm, and may wound the pleura and lung; also if the cannula, or tube, be retained for a long time necrosis of the rib is very likely to occur. In inserting the trocar it is desirable to follow the directions of the bulging—that is, if the abscess is pointing upwards, the trocar should be directed from below upwards, and *vice versa*; thus as contraction usually takes place towards the centre of the liver, the sac is brought as nearly as possible beneath the opening in the skin, pressure upon the tube is avoided, and drainage facilitated.

I did not in this case use the carbolic spray at the time of the operation, but by carefully washing out the sac with carbolic lotion and surrounding the opening with carbolized tow, the discharges throughout remained aseptic. As it is not possible in the time at our disposal to discuss fully the whole subject of the treatment of hepatic abscess, I have contented myself with drawing your attention to those points which appear to me of the greatest practical importance.

ABSTRACT OF

Wettsomian Lectures

ON THE

TREATMENT OF SOME OF THE FORMS OF VALVULAR DISEASE OF THE HEART.

Delivered at the Medical Society of London, Jan. 8th, 1883.

By A. E. SANSOM, M.D. Lond., F.R.C.P.,

Physician to the London Hospital, Senior Physician to the North-Eastern Hospital for Children, etc.

LECTURE I.

ENDOCARDITIS.

IN this course of lectures my plan will be to enunciate very briefly the bases on which I believe our therapeutics ought to rest. These are, in my opinion: (1) The teaching of morbid anatomy; (2) clinical observation of disease processes and their correlations. Then I propose to review (3) the lesson of the past as to treatment; and (4) to

adduce towards the elucidation of the various problems the arguments from analogy afforded by experimental investigation—a mode of inquiry rendered difficult, alas! by the stumbling-blocks which a false sentimentalism has placed in our way.

First, then, I will consider the teaching of morbid anatomy as to lesions of the valves of the heart. You will understand that I shall do this very briefly, for my object is merely to note them in so far as they may afford a guide to treatment, and when I speak apparently dogmatically, I do not make an assertion *ex cathedra*, but in the spirit of an inquirer after truth.

We will first consider the disease which most commonly affects the valvular apparatus of the heart and the adjacent endocardium—the disease known as *endocarditis*. In briefly reviewing its morbid anatomy, much will remain unsaid, but I shall treat it first from the standpoint of mere observation, leaving all speculative questions. I would classify the first changes in the endocardium which I shall notice as *exudative*. The curtains or cusps of the valves may be seen to be slightly swollen, and the endocardium to contrast by its dulness with the healthy portions adjacent. But the changes are most noticeable at the free edges of the valves, where may be seen isolated or agglomerated beadlike processes. Upon such processes may be observed sometimes little caps of fibrin. A thin section of a valve thus affected is seen under the microscope to differ from healthy valve structure in that its cellular elements are more numerous, and, especially towards the free edge, are closely aggregated. I wish to insist on the fact that in a valve so affected even the portions which seem to the naked eye unaffected are really infiltrated with cells; only the aggregation is greater at the free edge, where such caps of fibrin are often found attached. The beadlike eminences observed by the naked eye are, according to my view, indications of a more widespread inflammatory change in the valve than might be at first expected.

The second form of endocarditis, or properly-speaking valvulitis, to which I shall call attention, is that which I would term the *sclerous*, or fibrotic form. Here the valve, and it is the mitral which is affected in by far the greatest frequency, is thickened, but the thickening is not due to swelling of the soft tissue. It is felt to be hard and firm. The endocardium of the auricle, near the other valve, is found to be dense and white. The valve-curians, and often the cords and fleshy columns, are more or less rigid. A patch of the endocardium lining the left ventricle, and leading up towards the aortic cusps, is sometimes also found white and thick, and the aortic valves themselves may be seen to have undergone similar changes. In this form microscopic section shows that there is a gradual fibrous transformation of the neoplasm resulting in the production of a quasi-cicatricial tissue.

A third form of endocarditis which I think of practical importance to distinguish is that which is *secondary to endarteritis* (atheroma). In this form it is the aortic valves which are affected in a large majority of instances. Patches of soft flabby swelling may be seen in the lining membrane of the aorta, close to the aortic cusps, involving them in the change, and, perhaps, causing the inversion of one or more; or yellowish patches may be observed, in some cases covered by a soft pulpy material, the blood, perhaps, forcing its way at some softened spot between or within the arterial coats; or the root of the aorta may be hard and thick, the thickening being of cartilaginous consistence, and in such thickening the cusps of the valve may be

involved; or in like situation, and with like deformity of valves, there may be a bony or stony hardness, a calcareous change. The evidence obtained by microscopic investigation is to the effect that in the swollen soft patches are abundant exudation cells with a hyaline or slightly fibrillar matrix. These occur mostly as swellings of the internal coat, but Dr. Wilks has observed them in all the coats of the vessel. The yellow patches show fat granules and cholesterine crystals. There is evidently a fatty degeneration of the inflammatory neoplasm. In the fibrous or semi-cartilaginous variety there is more fibrillation and fewer cells, and in the hard and bony form there is a deposit of earthly salts in the interstices of the fibrous tissue.

The fourth form of endocarditis to which I shall call attention is that termed *ulcerative endocarditis*. Swollen and dull portions of the endocardium of the valve may be seen to present here and there a yellowish or greyish discoloration, and to be covered by a finely granular débris. The superficial endocardium in such situations has become necrosed. Through such breach blood may find its way, and, spreading between the layers constituting the valve, may form an aneurism thereof; or the ulceration extending through both layers the valve may be perforated. More commonly a considerable portion of the valve is eroded, and upon the eroded surface fibrine is deposited in the form of single or multiple vegetations. The finger readily detaches these vegetations, and the surface below them is found to be covered by a friable material.

Secondly, the rise and progress of endocarditis as evidenced by clinical observation. The fact which stands out pre-eminently in this connection is the association with rheumatism, acute and subacute. Amongst English observers (Fuller, Sibson, Budd, Latham, and others), the figures approximate tolerably closely and indicate that in acute rheumatism endocarditis becomes manifest in one out of every two or three cases. Continental observers, however, record a less proclivity, the figures of Bamberger, Lebert, Wunderlich, and Roth showing a proportion of one in five to eight cases. The statistics collated for me by Dr. Gabbett from the records of the London Hospital show that in 1880 113 cases of valvular complications were noted in 244 cases of rheumatic fever—a proportion of 46.3 per cent., and in 1881 170 in 295, or 60.6 per cent. The increasing proclivity to valvular complications with repeated attacks of rheumatic fever is well shown.

The first sign by which endocarditis is rendered probable is in my opinion a prolongation of the first sound of the heart, which may afterwards develop into a distinct systolic murmur. Such murmur is, however, not absolutely pathognomonic, for it may be due to regurgitation from adynamia of the left ventricle. Such modification is commonly heard directly the patient comes under observation. I have observed also as indicating signs reduplication of heart sounds, and in these cases a *presystolic* murmur subsequently develops. Rarely a diastolic aortic murmur is the declaratory sign. Endocarditis is by no means necessarily attended with pyrexia, nor even by any sign or symptom whatever referred to the heart.

I will now inquire concerning those cases of endocarditis which are not associated with a history of acute or subacute rheumatism. These may conveniently, for purposes of investigation, be divided into two classes: (1) those which are observed in early life, and (2) those which develop after maturity. In the latter class are the cases of gradual onset which involve the aortic orifice, and sometimes the mitral subsequently, which are

traceable to sub-inflammatory changes at the root of the aorta, and degeneration afterwards. In these cases the endocarditis and valvulitis are consecutive; they have no necessary connection with rheumatism, and their consideration may be conveniently deferred. The study of endocarditis as it occurs in the early periods of life is, I think, at the point at which our investigation has hitherto been advanced, a matter of very great importance. Almost every practitioner is familiar with the fact that cases of disease of the valves present themselves which have shown evidence of such disease for many years, from very early periods of the life of the patient, and yet inquiry fails to elicit that the subject of such disease has ever suffered from rheumatism in any form. It is surely a matter of importance, therefore, that we should endeavor to learn how such disease originates in the period of childhood. In acute and subacute rheumatism in the child the proneness to endocarditis is greater than in the adult. Typical rheumatic fever is much less common in the child than in the adult; the articular manifestations are slighter, but I consider the morbidity of the endocardium to be greater. Of thirty-two cases of acute and subacute rheumatism occurring in children under twelve years of age admitted into the North-Eastern Hospital during the past three years, twenty, or 62 per cent., presented signs of endocardial affection. The development of endocarditis, however, in the child has not so close a relation with the other phenomena of rheumatic fever as in the adult. It may precede, or may succeed even after long periods, the attack.

But there are other diseases besides rheumatism in the child with which endocarditis stands in close relation. These are chiefly scarlatina and measles. In relation with scarlatina endocarditis may occur either with or without the intervention of articular symptoms. Post-scarlatinal rheumatism is well known, and bears a close similarity to ordinary rheumatic fever; associated endocarditis is, therefore, rendered probable. But I have shown from recorded cases that such endocarditis may become manifest after scarlatina, not only without the intervention of articular phenomena, but long after the period of fever has passed, and during a time when there is no elevation of the temperature of the body, no pyrexia whatever.¹

Again, there is evident proof that endocarditis can arise in close relation with measles. I have recorded a case in which both pericarditis and endocarditis occurred a fortnight after the commencement of convalescence from measles. At this time a perilous attack of chorea developed. There was here no obvious manifestation of rheumatism nor hereditary tendency thereto. It appears to me that the influence of measles in predisposing to endocarditis has been much underrated, and *a fortiori* the frequent sequence of these diseases as observed in children becomes an agency, and that, as I think, very probable, not only to the production of the endocardial disease, but to acute rheumatism itself.

Excluding these causes, there yet remains a considerable minority of cases of endocarditis in children in whom no traceable disease has led up to the valve deterioration. The condition is only betrayed by various morbid conditions, the results or concomitants of the valvular disease. I have noted twenty-seven of such cases. They have been marked by (a) disorders of the nervous system: hemiplegia, hemianæsthesia, epilepsy, chorea; (b) disorders of nutrition: wasting, anæmia, etc.; (c) disorders of respiration or circulation: cough,

dyspnoea, or the usual phenomena of progressive cardiac failure. Sufficient is this evidence to prove, I think, that in the child endocarditis can arise and progress without special symptoms, without pyrexia, without the disturbing influence of any acute disease.

As regards the *pathogenesis* of rheumatic endocarditis, I do not think the evidence at all justifies the conclusion, that its first cause is extrinsic to the body or that it is of malarial origin and of the nature of an organized germ. On the other hand, there is much to prove that the "poison" is generated by a perverted metamorphosis, by retention of effete products in the blood. It is quite probable, I consider, that lactic acid is one, but not the only product capable of acting as the pathogenetic agent. Such agents may be many, between fibrin on the one hand and the excreted morbid acid on the other. It is not proven, but yet not improbable, that disturbance of a tract of the spinal cord—a postulated chemical coördinating centre—may be a mode in which the disorder can be originated and prolonged, as Dr. P. W. Latham has argued.

I must now approach another part of my subject and inquire concerning the efficacy of extant methods of treatment in regard to rheumatic endocarditis. It has been claimed of almost all methods of treatment of rheumatism that have been advocated, that they have been instrumental in controlling or preventing the cardiac complications of the disease. The individual experience of observers has been cited again and again to point the efficacy of this or that remedy or method in mitigating the chief danger of rheumatic fever. Yet proof of such vaunted efficacy has soon been found to be unsatisfactory, and it may be confidently asserted that no antidotal treatment is yet known—that we have, for instance, no drug which can influence endocarditis as quinine influences ague, or as mercury and iodide of potassium influences syphilis. The discussion so ably sustained in this Society during the last session, which has been fully reported, has put the claims of various forms of treatment of rheumatic fever to a numerical test. The results of treatment by rest and mint-water, by alkalies, by blistering, and by administration of salicin and its compounds were compared, and it is fair to assume that if any agent other than these had been efficient in the treatment of rheumatic fever or of endocarditis evidence would have made this apparent. The result of the discussion, which it is unnecessary to epitomize, was to show a strong concurrence of testimony to the effect that the administration of salicin or the salicylates very decidedly reduced the suffering and the fever of rheumatism, but in no marked degree influence the development of endocarditis and other cardiac complications. *Prima facie* this seems to be a strange conclusion, for one might imagine that an agent that reduced in such marked degree the pain and fever which must contribute to disturb the heart even if it had no decided effect upon the rheumatic process within the heart, would with great probability influence for good the inflammatory process in pericardium as well as endocardium. The conclusion is forced home, however, alike by individual experience, for we find that pericarditis and endocarditis are shown by physical signs to arise and progress in patients who are fully under the salicin treatment, and by statistical inquiry from large numbers of cases treated by the salicin compounds, compared with those treated in the presalicylic era, such as has been carefully followed out by Dr. Gilbert Smith. Dr. MacLagan, to whom the profession and the public are indebted for the introduction of agents which have at any

¹ Lectures in Medical Times and Gazette, Oct. 25th, 1879, p. 472.

rate been proved to contribute to the comfort of suffering patients, himself allows that the hopes that they would ward off cardiac complications have not been realized. I consider that there are strong reasons why a mode of treatment which is efficacious in rheumatic fever is powerless as regards cardiac complications. To put the matter clinically or practically. We observe, let us assume, a patient in a first attack of rheumatic fever. He presents (1) a murmur indicating an endocardial complication. I think I must have convinced you that such endocarditis may have arisen not during the attack from which he is at present suffering, but from the disease acquired insidiously at any time previously. It is obvious that any remedy would fail to influence the cardiac complication in such a class of cases. Or (2) a modification of sounds, or actual systolic murmur, developing at the apex, makes us suspect the present rise and progress of endocardial inflammation. But such may have its commencement long before the advent of the other symptoms, for no sign will betray the gradual swelling of a valve. A swollen valve is not necessarily incompetent. On the other hand, a veritable systolic murmur at the apex is no conclusive proof of endocarditis, for it may be due to adynamia of cardiac muscle. Here, then, is a double source of fallacy in the statistics of the cardiac complications of rheumatism. Or (3) the patient manifesting no evidence of valvular impairment is, at the termination of his attack of rheumatic fever, discharged as free from cardiac disease. I do not think that such conclusion is to be justified. A valve may be inflamed and give no evidence of incompetence, the patient may be discharged and show no signs of cardiac trouble, but a slow process of shrinking or of sclerosis may be going on; and when the patient next presents himself there may be undoubted evidence of endocardial mischief. This is, I consider, by no means of infrequent occurrence; and this is one reason why a second attack of rheumatic fever is attended with such notable evidence of a highly increased ratio of cardiac complications.

For such reasons as these, I think it is impossible—the sources of error being so numerous—that we can get from statistical inquiry satisfactory evidence as to the efficacy of different plans of treatment in warding off endocardial disease; and I dissent from those who hold that a remedy which is efficacious in the treatment of acute rheumatism ought to show, on numerical inquiry, a favorable influence on the correlated heart disease. I consider the treatment by salicin and the salicylates, even though no favorable results are manifest as regards cardiac complications, to be the most favorable to the patient of all forms of treatment hitherto known. In such cases it may be legitimately asked whether I adopt an altogether pessimist view of the treatment of endocarditis. Can nothing be done? My answer is, much; but it must be in the direction of *preventive treatment*. My own experience is strongly towards the conclusion that endocarditis is more prevalent, as well as more extensive and severe, among the poor than among the well-to-do. This question is one that might with advantage be put to the numerical test; we greatly want the evidence of the family practitioner to compare with that afforded by our hospital statistics. The predisposing causes to the advent of endocarditis, which as I have shown can arise without the intervention of obviously rheumatic phenomena, are most probably (1) exposure to vicissitudes of temperature, (2) an irregular and improper dietary. These are the impulses to a perverted nutrition, resulting in the retention within the blood of those excrementitious products which we may call “the rheumatic poison.” At-

tention to the clothing and proper feeding of infants and children constitutes in my mind, therefore, the treatment of the first importance as regards endocarditis. There is no need nowadays to insist on the importance of preventive treatment as regards the zymotic diseases. This is well recognized. Is it not quite as important as regards the subtle disease we are considering? I would, whilst recognizing the difficulties of such proceeding, strongly recommend the periodic medical examination of children, even though they present no obvious signs of disease.

Of no less importance is the treatment in regard to the zymotic diseases which are correlated with endocarditis—viz., scarlatina and measles. The subject of an attack of scarlatina should be watched with great care for long periods after convalescence. Moreover, the slightest sign of throat ailment, especially with children, should be looked upon with suspicion. I have no doubt whatever that in a large number of instances ulcerative tonsillitis of zymotic type occurs in children unnoticed and unknown, and that in many such a renal complication is instituted which is also neglected. The rise of endocarditis in such case is, as I have said, not during the period of fever. I do not recognize the influence of morbid germs in *directly* occasioning the inflammatory change in the valves. Such change is a consecutive and secondary effect. The teaching I would enforce, therefore, is that the subject of scarlatina, or of the allied forms of throat affection, should be watched, protected, dieted, and treated for periods much longer than is now usual. And as regards measles. There is, unfortunately, a widely-spread tendency to regard measles as a very slight ailment that requires little or no treatment. Experience tells, however, that it is not only the immediate precursor of bronchopneumonia frequently, and heart disease occasionally, but that it effects a deleterious change upon the powers of nutrition, which lasts, as in the case of scarlatina, for long periods. The subsequent treatment, therefore, of the subjects of measles should, in my opinion, be much more protracted than it is at present. Such is an outline of what I consider the common-sense treatment of the first causes of endocarditis. During its rise and progress in an attack of rheumatism, I prefer the treatment by salicin or the salicylates in sufficient doses (usually twenty grains every four hours, till subsidence of the pain and pyrexia, and afterwards the same dose thrice or twice a day). From the evidence of Dr. Isambard Owen, there is a good case in favor of combining with this the administration of full doses of alkalies. Vesication by the application of liq. vesicatorius in the left axilla, I think also of service.

It now only remains for me to allude to the clinical significance of *ulcerative endocarditis*, with regard to indications for treatment. It happens sometimes that this affection arises and runs its course with little or no evidence that the endocardium is impaired. Such cases often present a strong resemblance to typhoid fever. Here treatment is of no avail, the disease is uniformly fatal. By far the most frequently the disease is engrafted, as it were, on chronic disease of the valves. It appears to me that such cases can be divided into two classes, the infective and the non-infective. In the infective cases there are extraordinary disturbances of temperature, multiple emboli and septicæmic signs or even abscesses. It is in such that micrococci are discovered. They are, I believe, specific organisms, associated with some subtle zymotic influence or virus, as in the puerperal cases. It is not that the micrococci induce the endocarditis, but they complicate the already existing endocarditis by inducing necrosis of the dis-

eased tissue. In other cases, though nearly all are characterized by embolism, the proof of infection, and, as I think, the probabilities thereof, are wanting. In a case lately under my care in the London Hospital there was no marked pyrexia whatever, the temperature never exceeding 101° F., and for the most part keeping close to the normal. I consider it most probable that in some such cases the ulceration is induced by mechanical causes. Drs. Wilks and Moxon have pointed out that a great mass of vegetation may cause ulceration of the heart-wall by direct pressure, or a fibrinous clot swinging in the blood-current coming sharply into contact with the muscle, may by friction start an ulcer.* In like manner I think it very probable that a weighty vegetation, or a mass of vegetation, upon a valve may, by agitation in the blood-current, so disturb the nutrition of the endocardium, which constitutes its base, as to start the process of necrosis. The treatment of ulcerative endocarditis, when once established, is hopeless, but the lessons taught by a study of the cases are, I consider: (1) that more than ordinary care should be exercised to keep the subjects of valvular disease of the heart from possible sources of infection; (2) that any threatening of endocarditis should be treated by the most perfect physiological rest attainable; (3) that nutrition should be sustained to the highest degree practicable.

Clinical Lecture

ON

PREGNANCY NEPHRITIS.

By REGINALD SOUTHEY, M.D. F.R.C.P. Lond.,

Physician and Lecturer at St. Bartholomew's Hospital.

GENTLEMEN—I am about to direct your attention to a form of disease which is certainly rare, and of which too few examples pass under our notice in a general hospital. Medical men sometimes practice for years without seeing a case of pregnancy nephritis; and when they do encounter one, find how little formulated their ideas are on the subject, and how unprepared they are to give a prognosis or treat it properly, or offer a reasonable explanation of the evident close causal connection that exists between pregnancy and renal disease. Let me say a few words in preface about the malady. It assails women previously healthy in sequence to their becoming pregnant, begins insidiously without fever or pain, and proceeds to some grave symptom—rapid general dropsy, sudden convulsion, uræmia, or cerebral disturbance—before the patient is aware that anything serious is the matter with her. Mere albumen in the urine of a pregnant woman does not necessarily signify pregnancy nephritis. Abeille¹ found albumen in 1 out of every 10 pregnant women. Van Arsdale and Elliott² found it in 1 in 56, a proportion which appears to me more reasonable. Dr. Roberts, uniting the statistics of Blot, Meyer, Devilliers, and Regnaud together, infers the liability of pregnant woman with albuminous urine to eclampsia to be about 1 in 4. The eclampsia is usually not expected, although precursory symptoms, such as headache, vomiting, delirium, and clouded intelligence, are noticed in several recorded cases. As to the time of occurrence of the convulsions, which is the most dangerous of the

uræmic manifestations, various valuable statistics have been collected. Thus, the nearer to its natural term the pregnancy is conducted, the more likely, in these albuminous cases, is eclampsia to supervene. The subjects of pregnancy nephritis who are prematurely confined most probably escape the eclamptic complication. There are valuable figures collected by Von Wiegner, who tabulated 455 cases showing that the convulsions preceded the commencement of labour in 109 instances, attended the act of parturition in 236, and followed its completion in 110. Now to our case.

Annie B—, aged twenty-three, a domestic servant, was admitted into Faith ward for general dropsy, February, 1882. Her face, legs, abdominal walls, and skin everywhere were extremely anasarcaous. The eyelids were so swollen that she could scarcely look through them; her abdominal cavity also contained ascitic fluid, but besides this she was obviously pregnant as well, although she stoutly denied the imputation of it, for we were able to count distinctly the sounds of the foetal heart and feel the outlines of a child in utero. The catamenia had been absent for six months. There was evidence also of some hydrothorax on both sides, the fluid being largest in amount on the right side; the heart sounds were loud and clear.

History.—She had had scarlet fever at fourteen; otherwise perfectly good health. She told us her present illness began by swelling of the legs, which she first noticed three weeks ago, and was succeeded by cough and shortness of breath, her chief complaint on admission.

State on admission.—Besides her general anasarca and dropsy, her countenance was dusky, her lips somewhat livid, and her mental condition was very apathetic and drowsy. She was rational, but not reliable in her answers. Her pulse was 72; respiration 28; temperature 98·4°; tongue furred and bluish; appetite bad; bowels open, solid action; urine scanty, sp. gr. 1028, high colored, and containing one-quarter its volume of albumen. Her sight, she informed us, was bad, and had been failing for a week, not longer, and certainly was worse the day after her admission, for she then groped about for objects on her locker like a person nearly blind.

The diagnosis, so far as pregnancy nephritis was concerned, was not difficult. But what form of pregnancy nephritis was here, for all are not alike, either in their symptoms, their course, or their issue? and towards prognosis, the distinction which experience has taught me to draw between them severally is, in my opinion, very important. 1. There is eclampsia parturientium, a series of epileptic convulsions concurring with the act of parturition, and coinciding with highly albuminous scanty urine, or with anuria (total defect of urine), preceded by no well-defined or usually noticed symptoms of renal disease, for neither slight nor severe anasarca of the legs attending the later months of pregnancy can be accepted as incriminating evidence of prior or primary renal disease. 2. There is chronic Bright's disease, chronic insidious parenchymatous diffuse nephritis, complicated by pregnancy, quickened and rendered more imminently dangerous by uræmic symptoms, or local inflammatory complications, *pari passu*, with each week of advancing pregnancy. 3. There is pregnancy nephritis proper, a cortical glandular nephritis, an acute change in the nutrition of the renal epithelium, which commences sometimes as early as the third month of pregnancy, but more often in the sixth, and is attended by diminished urination, albuminuria, anasarca of face and limbs, retinal symptoms, uræmic symptoms, vomiting, neuralgia, lung oedema, asthma,

¹ Pathological Anatomy, 2nd Ed., p. 120.

³ *New York Journal of Medicine.*

mental perturbation phenomena, convulsions, and sometimes death; but is usually suddenly terminated by premature delivery and subsequent profuse diuresis, and complete recovery. Now, our case, proved to be of this last kind, and this is the form of which I have had most personal experience.

To return to our case. Mr. Barnes, my house-physician, instituted a careful examination of the eyes. He found the fundus of the right eye extremely hazy. The disc, except for a very pale ring at its periphery, was nearly of the same pink color as the surrounding fundus. The margin of the papilla was swollen, and the retinal veins somewhat large; but no hæmorrhages or retinal effusions were observed. Left eye: The disc was swollen, red, and indistinct, but better defined than that of the right eye; the veins of the fundus were enlarged; a dark spot of hæmorrhage was apparent on the outer side of the large descending vein. The patient took fluid nourishment well. She was examined by Dr. Matthews Duncan, who advised gentle purgation, and, if eclamptic symptoms supervened, the induction of premature labour. The fifth day after her admission, meantime making no complaint of labour pains, the patient asked for a bedpan, and told the nurse that she would find something in it—in fact, a dead foetus, to which she had given birth. This was on Feb. 14th. The after-birth came away naturally. The patient lost very little blood; but, in consequence probably of the labour-pains and straining, there was slight hæmorrhage in each upper eyelid, and the conjunctivæ were very cedematous, and both eyes very painful and hypersensitive to light. The temperature was never elevated, the lochial discharge established itself, the general cedema rapidly subsided, her face and legs were obviously less swollen the second day after her delivery, and she passed at least two pints of urine; specific gravity 1025, still containing a quarter of its volume of albumen. She complained of frontal headache and of her eyes, and her sight was so bad that she could only uncertainly count fingers held up between her and the light. The patient took nourishment well, and the only medicine ordered was effervescent tartrate of soda.

Feb. 17th: Passed 85 oz. of urine.

			sp. gr.	1020	album.	¼
18th	"	120 oz.	"	"	10.2	"
19th	"	120 oz.	"	"	10.2	"
20th	"	110 oz.	"	"	10.2	"
21st	"	104 oz.	"	"	10.15	traces
22nd	"	124 oz.	"	"	10.15	traces
23rd	"	132 oz.	"	"	10.13	traces
24th	"	100 oz.	"	"	10.17	nil

On the 18th the note says: Slept well, still headache, tongue clean; pulse 100; respiration 36; temperature 98°. Sight no better. Patch of white effusion on apparent inner side of right disc, which is still red and swollen: Extensive detachment of lower half of right retina in the form of three large cusps. Left eye: Retina red and swollen as before labour, but two hæmorrhagic effusions now visible. On the 28th the sight of both eyes was obviously improved; that of the left was fairly good; right still much impaired.

On March 6th we obtained another ophthalmoscopic examination of her eyes, when, to my surprise, no trace of the previously detached half of the right retina could be discovered; there was intense swelling of the disc with blurring of its edge; the whole fundus was cloudy and indistinct in its deeper layers, and several patches of effusion here and there surrounding, and also surrounded by, spots of pigmentation, could be seen. The seat of previous detachment and bulging of the retina was the part where most pigmentation was apparent.

From Feb. 24th she ate a mutton chop daily, and took a good milk dietary and custard pudding.

The lochial discharge ceased early. All albumen had disappeared from the urine within a week after her delivery. She took a steel mixture during her convalescence, and was discharged quite well and with no complaint about her sight, and able to read the print of the daily papers, on March 15th.

Apart from its interest as a case of pregnancy nephritis, this woman's record shows how completely acute retino-choroiditis and partial detachment of a large portion of a retina may be recovered from. *Desinit causa tollitur effectus*. Unfortunately, in other forms of Bright's disease, while we encounter the same retinal complication, we seldom find a similar capacity of recovery.

So early as 1840, Rayer (vol. ii., p. 399) called attention to pregnancy nephritis, described its principal symptoms, and noticed the tendency of the mother to die of convulsions, and of the foetus to be born prematurely and dead. Lever, in Guy's Hospital Reports, 1843, observed that the urine of nine out of ten parturient women who had convulsions was albuminous. Frerichs, in 1851, first attributed the eclampsia parturientium to uræmic intoxication; and from that time to the present few forms of renal disease have been more written about; the symptoms being calculated to attract attention, a large proportion of the eclamptic cases dying, and a fair proportion of those who survived the act of parturition a week recovering.

In a clinical lecture it would be impossible for me to do justice to the various speculations that have been ventured on the etiology of the nephritis. Many accoucheurs still attribute it to mechanical pressure, notwithstanding Bartels' arguments to the contrary. That the enlarging uterus should press upon the renal veins is scarcely intelligible; that it might press upon the neck of the bladder and increase the urine pressure on the ureters, the pelvis of the kidney, and the tubuli uriniferi, is far from unreasonable however. In favor of mere mechanical pressure as its cause are the established statistical facts:—(1) That this nephritis happens mainly, if not only, in the latter months of pregnancy; (2) that it affects primiparæ principally; (3) that it complicates twin rather than single pregnancy; and (4) that the anasarca and albuminuria subside rapidly after parturition. I can only mention, not discuss, here the primary impurity of the blood theory, Bartels' uræa excess, Gubler's albumen excess, leukæmia and hydræmia—all incident to pregnancy; Peter's overworked kidney theory, and the still more recent vasomotor spasm of the renal arteries theory—these may do duty to explain some particular cases of eclampsia; they will not explain all the urinary symptoms of pregnancy nephritis, or the pathological changes most commonly found in the kidneys of those who die.

From Leyden and Wagner I give you the ordinary morbid changes which are found in the kidneys of typical pregnancy nephritis (Wagner, "Morbus Brightii," p. 196). The kidneys are to naked-eye inspection little altered, slightly enlarged, rather bloodless than blood gorged, a little soft to feel, and a little yellowish colored. Under the microscope, the tubuli are observed a little dilated, their epithelium swollen, and either finely granular from fat or albumen, completely filling up some of the canals of the tubules. Only a few casts are seen *in situ* in the tubules. The glomeruli are mostly bloodless, the capsular epithelium is in some detached, in others there is a half-moon of albuminous material between the capillary tuft and capsule. The stroma of the kidney is normal or cedematous. In a few cases (Virchow and Bartels are agreed on their extreme rarity) the ordinary appearances of hæmorrhagic nephritis have been found, and Litzman observed several times recent changes like those described above welded

evidently upon kidneys which presented characteristic evidence of old chronic diffuse renal disease. The following case, taken from an article by Leyden, confirms the pathological accuracy of the description above given from Wagner:—

A. J—, aged twenty-eight, a previously perfectly healthy woman, passed through a normal gestation in a first pregnancy up to the seventh month, when she noticed that she required to urinate unusually frequently. Shortly afterwards her ankles began to swell and the dropsy rapidly extended to her legs, genitalia, and back. She complained of the weight of her legs and shortness of her breath. Temperature 36.5° C.; pulse 72, regular, of moderate high tension; heart and lungs normal; urine 1,000 cc. per diem, sp. gr. 1035, thick, coffee-colored, presenting moderate sediment, but containing much albumen. The sediment contained no red cells; some white ones, free fatty renal epithelium, and hyaline casts. About a fortnight later labour came on suddenly, the swollen labia suffered some laceration; rigors occurred the day after, septicæmia and death on the sixth day.

Post-mortem Examination.—(The state of the kidneys alone need our attention). Left kidney: Swollen surface of grey-yellowish color, slightly oedematous; veins full; section anæmic; substance doughy; medullary portions, especially the ends of the cones, pale. Right kidney similar, but rather more fatty-looking, doughy, enlarged; its pelvis and ureter obviously dilated. The microscope demonstrated some casts *in situ*; fatty infiltration of renal epithelium; no alteration of vessels or glomeruli; no nuclear proliferations, but here and there a few groups (foci) of micrococci in the stroma (patient died of septicæmia) between the straight tubes of the pyramids. The writer says that these appearances differ *in toto* from scarlatinal nephritis; there is no venous hyperæmia, rather arterial anæmia, and secondary to it fatty necrosis of renal epithelium.

A point I wish to insist on, even if my own case has not illustrated it enough, is that the kidney in true pregnancy nephritis does not suffer any irreparable injury; that its disturbance is mainly functional at first; that less urinary water is secreted; and that what is secreted is of high specific gravity, high color, but affording little sediment, and seldom blood; that later on the evidence is forthcoming of nutritional failure in the renal cells. The most characteristic features of the malady agree entirely with my daily clinical experience of ordinary acute parenchymatous nephritis—scanty high-colored urine, with little sediment, but having a large percentage amount of albumen. As the case goes on from first appearance of dropsy and albuminuria, both these steadily increase, until convulsions, or premature parturition, or both these together, ensue. The rapidity with which the dropsy disappears and the urine becomes normal again after parturition, was noticed years ago by Regnaud and Devilliers, who recorded a case in which all albumen had disappeared fourteen days after delivery. In our own case six days after delivery the woman's urine contained not a trace; and although for three weeks longer we were able to find a trace usually, yet this was of small pathological importance, far too little to signify much. She was passing a healthy amount of urine and of urea, and no albumen in her discharge. *De futuris non est predicandum.* The prognosis for her is good, unless she becomes pregnant again, when the same nephritis is apt to repeat itself. Further experience teaches us that while with each succeeding pregnancy dropsy, al-

buminuria, and uræmic complications recur, the woman becomes more tolerant of her fœtus, the nephritis is continued for a longer time, and the damage to the kidney is more extensive and more apt to pass on to chronic nephritis when delivery is over. Indeed, I can record one case in a relation of my own, who suffered pregnancy nephritis with three successive pregnancies. The first fœtus was born somewhere short of the sixth month, but had been dead six weeks at least; the second was born in the seventh month dead; the last was carried to term, born alive, and is now alive. Between the first two pregnancies all albumen disappeared from her urine; after her last pregnancy and delivery albumen remained persistent until her death by uræmia.

Advice upon treatment.—Distinguish between the three varieties of pregnancy nephritis already noticed. Eclampsia parturientium with albuminous urine, but without notable dropsy, is relieved by chloroform, chloral, amyl nitrite, nitro-glycerine, bloodletting, warm baths, by all those things which relieve spasm, by completed delivery. Chronic Bright's disease, complicated by pregnancy, is best treated upon the ordinary plan for Bright disease, and its several accidents, by hot baths, warmth, careful dietary, gentle purgation. True pregnancy nephritis demands the induction of premature labour, the earlier the better, and requires that the medical man should plainly inform his patient of the risks to life entailed by any future pregnancy. The dropsy may also require relief by draining with fine cannulas, to avoid the risks of laceration of the genitalia and invitation of septicæmia.

ABSTRACT OF

Lecture

ON THE EVOLUTION OF THE STETHOSCOPE.

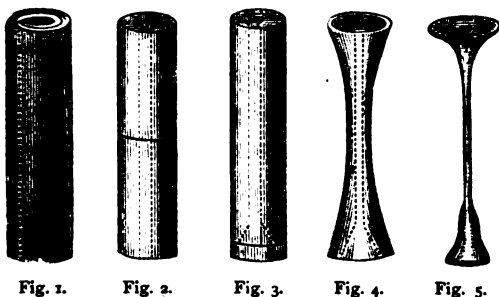

By SAMUEL WILKS, M.D., F.R.S.,

Physician and Lecturer on Medicine, Guy's Hospital.

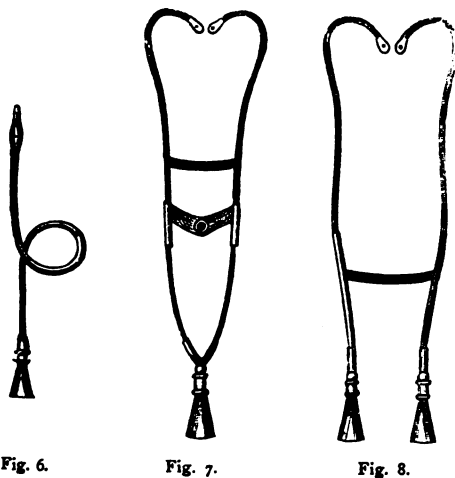

INSTEAD of placing on the table every imaginary form of stethoscope manufactured out of every possible material gathered from the shops of the instrument makers, I will carry you back to the origin of the stethoscope, and you will see how, on the principle of selection and the survival of the fittest the primitive instruments have departed from the scene and are now only to be found amongst the fossilized curiosities, the relics of former ages, on the antiquated shelves of some very old medical practitioner. The stethoscope, as you know, was invented by Laennec. He relates how in the year 1816 he happened to recollect a well-known fact in acoustics of solid bodies conveying sound, and he goes on to say: "Immediately on this suggestion I rolled a quire of paper into a kind of cylinder and applied one end of it to the region of the heart and the other to my ear, and was not a little surprised and pleased to find that I could thereby perceive the action of the heart in a manner much more clear than the application of the ear." "The first instrument which I used was a cylinder of paper formed of three quires completely rolled together and kept in shape by paste." Laennec then goes on to describe how he copied this roll of paper in wood, metals, glass and other substances, and finally he says: "In consequence of these various experiments I now employ a cylinder of wood an inch and a half in diameter and a foot long, perforated longitudinally by a bore three lines wide and hollowed out into a funnel shape to the depth of an inch and a half at

one of its extremities. It is divided into two portions, partly for the convenience of carriage and partly to permit its being used of half the usual length. The instrument in this form—that is, with the funnel-shaped extremity—is used in exploring the respiration and rattle; when applied to the exploration of the heart and voice it is converted into a simple tube with thick sides, by inserting into its excavated extremity a stopper or plug traversed by a small aperture and accurately adjusted to the excavation. This instrument I have denominated the *stethoscope*.

Fig. 1 represents Laennec's roll of paper, and Figs. 2 and 3 the copy of this in wood as he de-

scribes. The latter figure is drawn from an instrument kindly given me by Dr. Galton, of Norwood, being the stethoscope long used by his father. It does not separate into two pieces, but contains the plug which can be removed so as to leave the end hollow. Fig. 4 is the same instrument with the sides cut out to make it lighter and more elegant, the ear piece being the same as before and the mouth also hollowed out. This was the stethoscope used and recommended by the late Dr. Hughes. By making the instrument still more elegant and slender we have the modern stethoscope

in endless variety, as in Fig. 5. It is thus very evident how the modern instrument has been framed out of the original block of wood which was made the counterpart of Laennec's roll of paper.

I know not who invented the instruments with flexible tubes, but I have no doubt that a search into medical history could tell us. I remember, however, that the first flexible stethoscope which I ever saw was the one depicted in Fig. 6, and used by Dr. Golding Bird when he saw out-patients in

the year 1843. Being much crippled with rheumatism, and therefore not wishing to rise from his chair, he found this instrument very convenient; he also was enabled to pass the ear-piece to gentlemen standing near him, whilst he held the cup on the part to be examined. I always thought it was his own invention. But, whether so or not, I do not think any great effort of genius was required to frame a flexible instrument, and then adapt it for the use of one or two ears. This being done, the next step would be to make two mouth-pieces to apply to the chest at different spots. Various modifications of these instruments have been made of late years, but the first notice of them I have any knowledge of in my reading is to be found in a letter to *THE LANCET* of Aug. 29th, 1829, by Mr. Comins, of Edinburgh, headed "A Flexible Stethoscope." This was only twelve years after Laennec's invention. It is difficult from his description to picture the instrument, but it seems to have been composed of jointed tubes, and made for two ears as well as one. Mr. Comins expresses his surprise that the discoverer of mediate auscultation did not suggest a flexible instrument, as he says "it can be used in the highest ranks of society without offending fastidious delicacy."

A very interesting fact was first pointed out to me by Dr. Andrew Clark, with respect to a peculiarity of the binaural in the objective appreciation of sounds; that if each ear-piece be separately used, and any sound be made near the mouth-piece, it is heard in the ear itself, but if the two pieces are employed together the sound is heard at the spot where it is produced. The fact is very interesting in a physiological point of view, and further corroborates the theory as to the value of a double set of senses, or, in a word, of the body being made up of two halves, for just as the two hands feeling different parts of an object gain an idea of extension, and the two eyes by obtaining different views of any substance get a knowledge of its solidity, so in the same way the two ears listening to the same sound more thoroughly appreciate its objectivity.

If you look at this series of drawings you may perceive but little resemblance between the first figure and the last, but take them one by one and you will see that the figures are really progressive. My story of development is not imaginary, but historical.

Clinical Lecture

ON

THE MECHANICAL TREATMENT OF CARIES OF THE LUMBAR VERTEBRÆ.

Delivered on December 7th, 1882,

By Dr. M. JOSIAH ROBERTS,

Instructor in Orthopædic Surgery and Mechanical Therapeutics in the New York Post-Graduate Medical School, Visiting Orthopædic Surgeon to the City Hospitals on Randall's Island, etc.

GENTLEMEN—Let us examine the patient before us, with the hope of eliciting facts that will be of service in determining upon a plan of treatment. To save time I will tell you that this little four-year-old girl is suffering from chronic spondylitis of the first, second, and third lumbar vertebræ. The disease has existed for more than a year. It is slowly but surely affecting a solution of anterior vertebral continuity, while the posterior part of the column has remained intact. The arches and spinous processes of the involved vertebræ retain n

ing their integrity, there is a sinking of the bodies of the healthy segments of the spine above, and a forward curvature of that part of the column. As a result we have a corresponding posterior projection, which in this case, though well marked, has not proceeded so far as to render its ultimate obliteration hopeless. If we closely watch our little patient as she moves about from place to place, picking up pennies from the floor, you can observe two things. First, all her movements are conducted with unusual care for a child, and with great regard to the avoidance of any sudden motion or jarring of her body; secondly, owing to a spasm of the muscles of the back, there is no lateral or antero-posterior flexion and extension in the lower dorsal or lumbar regions. With her spine held rigid she squats upon the floor instead of bending over in the usual manner. Upon placing her in the ventral decubitus, and attempting backward extension of the dorso-lumbar vertebræ, we are at once met with opposition on the part of the tetanized muscles. Furthermore, the patient shows evident signs of discomfort. There is a reflex muscular spasm which prevents movement of the vertebræ. This condition of reflex spasm, securing articular immobility, can also be observed, as I have told you, in cases of osteitis of the hip, knee, or ankle. It is said to be Nature's method of placing the joint at rest and securing freedom from irritation to the diseased structures, which would otherwise result from articular motion. Upon this observation alone has been built up the prevailing system of mechanical therapeutics as applied to the treatment of chronic inflammations of the joints. To carry out this idea, "fixation" splints and "absolute immobility" splints and dressings have been devised for all the principal joints of the body, and are to-day in use throughout the civilized world.

There still remains another principle which is largely used in mechanical treatment of articular inflammations, which we have not yet elicited from the examination of our patient. If, with the diseased segments intervening, we make traction upon the spine in opposite directions (extension and counter-extension), and continue it for a sufficient time, we will find that the tetanized muscles will gradually soften and the patient will experience a greater degree of comfort and less apprehension. This observation has in recent times added another idea to the mechanical treatment of articular diseases—viz., that of extension for the relief of reflex muscular spasm. There are, therefore, two principal ideas involved in the prevailing methods of mechanical treatment: "traction" (extension) and "fixation," and these two ideas have been based upon the observations we have just made.

The point which I wish to make now is that these observations, though correct so far as they go, do not place us in possession of the whole truth. In carrying out this idea of extension, surgeons have generally failed to recognize the fact that the "extension" enforced by means of their mechanical appliances was not the same kind of extension which they had previously made with their own hands, and ascertained to be so acceptable to the patient. Manual extension is elastic; the prevailing mechanical extension is rigid. Let us examine our little patient still further, and see if we can elicit other facts which will point to wider truths and serve as guides to more rational treatment. As she stands in front of me I place my hand upon her thorax, just under the armpits, and lift gently upwards. Holding her with a firm and steady hand in this position, let us observe the result. At once she says "that feels good." In support of the truth of her statement let me inci-

dentally tell you what happened when I first suspended her some weeks ago for the purpose of taking a plaster mould of her body. So great was the relief afforded that within two or three minutes after she was placed in the apparatus and the superimposed weight removed from the diseased vertebræ she fell asleep, and though we continued our work, she remained in this condition until she was taken out of the swing.

Continuing to hold my little patient in this position, the reflex muscular spasm which has existed all along is gradually and surely overcome, and now my assistant, laying hold of her pelvis, makes forward, backward, and lateral movements of the spine in the affected regions, and as you see, apparently without the slightest inconvenience or discomfort to the patient. Thus we have demonstrated that "fixation" of the diseased vertebræ is not essential to the comfort of the patient, and that manual "extension" (which is necessarily elastic extension), combined with thorough support, are really the important factors in overcoming reflex muscular spasms, abolishing the feeling of apprehension and affording entire comfort to the patient.

Now, let us summarize the results of our observation. By efficient manual extension and support, relieving the involved segments of the spine from superimposed weight, we have, without "fixing" or "immobilizing" the carious vertebræ, secured entire comfort to the patient. The traction used to overcome reflex muscular spasm has been made with our hands, and hence has necessarily been elastic; there has been no rigid extension or fixation, only efficient support and elastic extension; neither have we interfered in any way with the proper performance of function by the healthy part of the spine. Could this condition of perfect comfort, so easily brought about by skilful manipulation of the inflamed vertebræ, be prolonged indefinitely, all must agree that it would be of the greatest advantage in promoting speedy recovery. We would thus be enabled at once to so circumstantiate the diseased spine that its motions would not be materially interfered with, and hence an important aid to the maintenance of a normal circulation would be retained throughout the period of treatment. The point which I here wish to emphasize is that articular motion throughout the body, both in the lower animals and in man, like the analogous movements in plants, is of much greater importance than has hitherto been supposed. It aids in the maintenance of a normal circulation, and hence in supplying the requisite nutrition and sustaining a favorable temperature for the growth and development of the individual, the renewal of tissues subject to successional decay, and the carrying on of reparative processes in case of disease. Furthermore, I shall demonstrate to you, that articular motion in disease, in conjunction with muscular action, can, by the aid of properly constructed mechanical appliances, be made to subserve the same general and local purposes which it does in health. One of the main features of this disease, as I have already pointed out, is the lowering of general and local nutrition. Hence, if we can by any possible means secure all the benefits which the united testimony of the profession have ascribed to "rigid extension" and "fixation," without "fixation" and without "rigidity," we will have at once more nearly approximated the condition of health, instead of having imitated the conditions we find in disease. We will have thus gained a great practical point, for "fixation" of a joint necessarily has a depreciating influence upon the local nutrition, and "rigid extension" does not reduce the jar incident to locomotion to the minimum.

We must substitute some mechanical device for this manual support, and for obvious reasons it is important that the patient be permitted to walk; that the support used be portable. To accomplish this by means of a single splint or apparatus, and to have the force which is exerted upon the spine in the various directions elastic, as it is when the hands are used for support, would seem to be a somewhat difficult mechanical problem to solve. That this is possible I wish now to demonstrate.

As I have elsewhere described,¹ the dressing to be worn can be applied directly to the patient, but for reasons which I cannot here discuss, the plan that I shall now employ is to be preferred. It is essential to get an accurate cast of the body upon which we can fashion our mechanical prop, so that it will fit the patient when applied. To obtain a cast we must first make a mould of the body. A tightly fitting knit shirt is now drawn over the cast, and we proceed to apply over it rollers of plaster bandage. Having applied a thin but uniform layer of gypsum over the entire cast, four pairs of light steel brackets are placed in

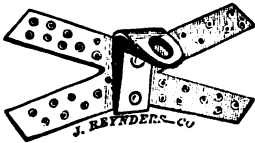

Fig. 1.

position upon it. These have thin perforated sheet-copper arms attached to them, in order that they may be securely held in position by layers of plaster bandage passed over them (Fig. 1). They are arranged in pairs one above the other (*vide*

Fig. 2.

dotted lines, Fig. 6), and temporarily held in place with a rubber band (such as is used to hold bundles of papers together), slipped over the cast.

¹ The Medical News, Oct. 14th, 1882.

Two pairs of brackets are placed behind, one upon either side of the spine, and one on either side of the body, in front of the arms. These brackets are for the purpose of retaining the elastic spinal extension bars, presently to be described, in position. A wet roller, saturated with gypsum, is now carried over the brackets, the projecting part of them only remaining uncovered. This holds them securely in position. When the dressing has become thoroughly dry a circumferential division of it and the shirt into an upper and lower segment is made at the smallest part of the waist. A longitudinal section, four or five inches in width, is next cut out of each segment in front. This permits of their easy removal from the cast without disturbing their shape. As will be seen later on, the same is true in regard to their application to, and removal from, the patient. At this stage we

Fig. 3.

have to call in the aid of an instrument maker. It will be his business to fit and attach metallic clasps to these segments. The clasps extend across the space left by the removal of the wide section of plaster dressing in front, thus completing the circumference of the body. Three of these are re-

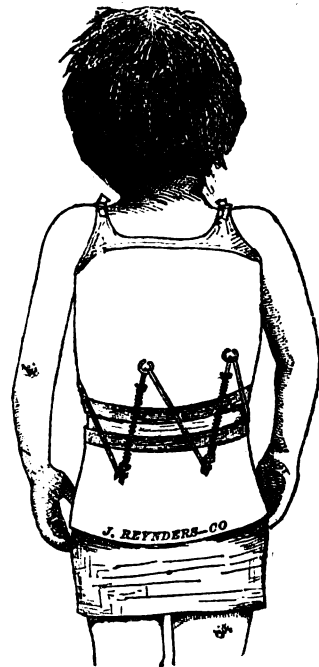

Fig. 4.

quired, two for the upper and one for the lower segment (*vide* Fig. 2). The ends of these clasps, upon one side, are secured to the plaster dressing by hinges; and upon the other side are kept from sliding upward or downward by steel pins projecting through slots made in them. When the segments are applied to the patient, the clasps are closed and secured in position by means of strong bands of elastic webbing buckled over them, as

can be seen in Fig. 2. This arrangement permits of the easy removal and reapplication of the segments at the pleasure of the surgeon. The rubber bands admit of the necessary expansion of the thorax with each inspiration, and at the same time the efficiency of the support is not invalidated. I should also call your attention to the fact that the clasps are curved, so as to correspond to the contour of the chest and abdomen. This prevents undue pressure upon these parts, thereby avoiding

through which the extension bars pass are large enough to admit of a very considerable amount of motion, while at the same time continuous elastic extension of the spine is maintained. You will observe that, by means of this mechanical appliance, we have placed the spine under very nearly the same conditions that it was when I extended it with my hands, and my assistant made forward and backward movements of the involved part.

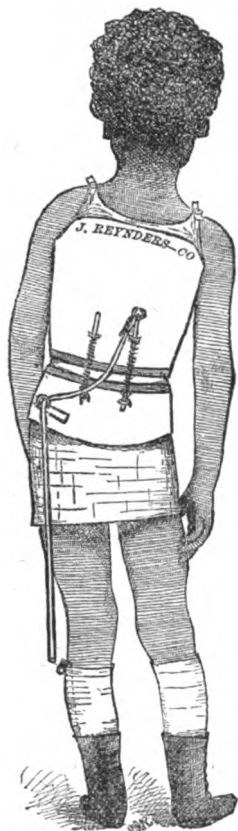

Fig. 5.

Fig. 6.

the objectionable feature common to all corset casings used in securing spinal supports in position. The segments having been placed in position on our little patient, and held by the bands of elastic webbing as above indicated, we now adjust the elastic extension bars. These are four in number. They consist of steel rods turned up at one end, as shown in Fig. 3. Each is provided with a nut and strong spiral spring. They are secured in position by passing their upper and lower ends through the perforations in the projecting part of the brackets, that have been previously embedded between the layers of plaster bandage (Fig. 4). The weight of the body, which is now sustained by the upper segment resting on the springs, serves to keep the extension bars in place. With a wrench the nuts may be moved up or down, and any desired amount of elastic extending force exerted. The improved position gained by suspension is thus preserved. By moving up the nuts from time to time, the kyphotic curve may be still further reduced without producing the slightest irritation. The perforations in the brackets

When rotation of the spine exists in conjunction with posterior curvature, as in this case, it can be very readily overcome in the following simple manner. To the summit of one or more of the extension rods, a nut, bearing two arms curved upward so as to make almost a complete ring (Fig. 4), is screwed. Rubber bands, such as are procurable at stationery stores, are now passed from the summit of one steel rod to the base of another, as seen in the figure. It should be remembered that these do not oppose the action of the steel springs, as would be the case if they were attached directly to the upper and lower segments of the jacket. They are attached to opposite ends of rigid steel bars. Any desired amount of elastic rotating force can thus be exerted, while at the same time continuous elastic extension of the spine is maintained.

Occasionally you will meet with cases in which the spinal column will be tilted to one side (Fig. 5). This is not unfrequently due to unilateral weakness of the muscles of the lower dorsal and lumbar regions. The improved position gained

by suspension is not maintained, no matter with how much skill the dressing is applied. And for this reason the power of the spinal lever is not applied below, or external to the weakened muscles. Were it practicable to carry a rigid spinal prop below the hip joints down upon the thighs, the improved position of the spine gained by suspension would be readily maintained. In a case such as is represented in Fig. 5, it will be found by placing the forefinger of one hand under the right axilla, and that of the other on the left hip, and exerting slight cross pressure, the patient will at once assume the upright position. As a permanent substitute for this finger pressure, I have used with entire satisfaction the following appliance. In the centre of a perforated strip of light tin about four or five inches long and three-eighths of an inch wide, a short thin piece of steel plate bearing a small ring is soldered. During the application of the dressing to the plaster cast one of these is incorporated between the layers of bandage over the left gluteal region, as shown by dotted lines in Fig. 5. As is also shown in the same figure, a nut of the form already described is screwed to the top of the extension rod on the right side of the spine. To this is attached one end of a long solid rubber cord, six or seven millimetres in diameter. The other end is passed through the ring which projects from the surface of the jacket below, and then attached to the shoe. A strip of non-elastic webbing, long enough to reach from the ankle to the knee, is sewed to the top of the shoe on the outer side. This is passed to the inside of the stocking through a button-hole in it just above the upper margin of the shoe. The free end of the strip of webbing is provided with a ring. Through this ring the lowest end of the elastic cord is passed and drawn sufficiently tight to overcome the distortion, when it is fastened by a simple half hitch or knot. This elastic cord does not oppose the lifting action of the spiral springs as it would were it attached directly to the upper segment of the jacket.

Original Papers.

PNEUMONIA.¹

By FRANCIS DELAFIELD, M.D.,
Professor of Pathology and Practical Medicine.

WE use the word pneumonia as a general term to designate the inflammations of the lungs. Anatomically there are four varieties of pneumonia: intra-alveolar pneumonia, interstitial pneumonia, the broncho-pneumonia of children, and tubercular pneumonia. You will observe that I do not use the words croupous and catarrhal pneumonia, and this is with design, for I believe that these terms are utterly inappropriate when applied to inflammation of the lung, and have led to much unnecessary confusion.

The most practical division of pneumonia, however, is according to the clinical groups in which the cases present themselves to us. We will, therefore, describe: The lobar pneumonia of adults; the secondary and complicating pneumonia of adults; the pneumonia of heart disease; the interstitial pneumonia of adults; the broncho-pneumonia of children; acute tuberculosis of the lungs; acute pulmonary phthisis; chronic pulmonary phthisis.

¹ A lecture delivered at the College of Physicians and Surgeons, New York.

The Acute Lobar Pneumonia of Adults.—The inflammatory process regularly attacks at the very first a considerable portion of one or both lungs. The situation of the disease can be seen from the following figures given by Juergensen from an analysis of 6,666 cases: Right lung, 53.7 per cent.; upper lobe, 12.15; middle lobe, 1.77; lower lobe, 22.14; whole lung, 9.35. Left lung, 38.23; upper lobe, 6.96; lower lobe, 22.73; whole lung, 8.54. Both lungs, 8.07; both upper lobes, 1.09; both lower lobes, 3.34 per cent. In rare cases nearly the whole of both lungs will become inflamed at the very outset. The inflammatory process involves regularly the air vesicles, air passages, bronchi, interstitial connective tissue, and pulmonary pleura. It is customary to describe the inflammation as passing through four stages: congestion red hepatisation, grey hepatisation, and resolution.

Congestion.—This stage usually escapes our observation for the reason that the patients do not die until later in the disease. The best example of the lesion that have I seen occurred in a woman, who died five hours after the initial chill. The right upper lobe was found firmer and more consistent than the rest of the lungs, but not hepatized. It was moderately congested and oedematous. The air vesicles contained a little granular matter, a little reticulated fibrine, a few pus cells, and a few epithelial cells, but not enough to fill the vesicles. There was a large number of white blood-globules in the capillary bloodvessels, and a swelling of the epithelial cells on the walls of the air vesicles. This first stage of congestion lasts but a few hours and is succeeded by

Red Hepatization.—The lung is now solid. Its cut surface, when fresh, is dry, granular, and red. The granules correspond to plugs of inflammatory matter which fill the air vesicles, air passages, and small bronchi. These plugs consist of pus cells, fibrine, epithelial cells, and red blood-globules. The air vesicles are not only filled, but distended by these inflammatory products, so that the inflamed portion of lung is voluminous and may compress the uninfamed portions. The interstitial connective tissue between the lobules of the lung is infiltrated with pus and fibrine, the pulmonary pleura is coated with fibrine. Of the fatal cases of pneumonia, in which I have made autopsies, about one-fourth have died in the stage of red hepatization, and the duration of the disease in these cases has been from twenty-four hours to eleven days.

Grey Hepatization.—The lung remains of the same consistence, solid and un aerated, but its color changes. Portions gradually change from red to grey, so that the lung is first mottled red and grey, and then completely grey. The pulmonary pleura continues to be coated with fibrine; the small bronchi, air passages, and air vesicles are still filled with pus, fibrine, and epithelium, and the interstitial tissue is still infiltrated with fibrine and pus. The only changes are that the red globules have lost their coloring matter, the bloodvessels contain less blood, the products of inflammation commence to undergo granular and fatty degeneration. I have found that about one-half of the fatal cases die in the condition of mottled red and grey hepatization, and about one-fourth in the condition of complete grey hepatization. The deaths with the mottled lungs occurred from the second to the eighteenth day, with the grey lungs from the fourth to the twenty-fifth day.

Resolution.—If the patients recover, the lung passes from the condition of grey hepatization into that of resolution. This stage of the inflammation usually escapes our observation, but occasionally patients die from accidental causes, and

in this way I have seen a few examples of this condition. The lung is no longer completely solid or completely grey, but there is a mottling of solid grey and aerated red portions of lung. Some of the air vesicles are completely empty, some contain a little granular matter, some fatty epithelium and pus, some are still filled with the products of inflammation.

The lung may remain in the condition of gray hepatisation for two or three weeks. It then becomes very white and dry, but there is no special change in the inflammatory products. I can see no reason for believing that this form of pneumonia ever passes into the condition of cheesy degeneration.

There are rare cases of lobar pneumonia in which fibrine is produced in unusually large amount, portions of lung tissue are compressed and become necrotic. In this way little cavities are formed containing fragments of dead lung tissue. Later the walls of these cavities are infiltrated with pus, so that abscesses are formed.

It is also possible for the inflammatory process to be characterized by an unusual production of pus, and even an infiltration of the walls of the air vesicles with pus. But I have never seen this condition reach such a degree as to form abscesses. The small bronchi are regularly filled with pus and fibrine, and in some cases the inflammation of the large bronchi becomes quite a feature of the disease. The inflammatory process may be catarrhal with a production of mucus, or croupous with the production of large cords of fibrine, which fill the bronchi. The pulmonary pleura is regularly coated with fibrine, but in some cases the pleurisy is developed to an unusual degree. Both pulmonary and costal pleura may be coated with a thick layer of fibrine and pus, and the pleural cavity may contain a considerable quantity of serum.

In rare cases lobar pneumonia is followed by gangrene of the lung. It is still unknown how this change is effected.

From what has been said it is evident that in lobar pneumonia we have an example of that form of inflammation in which the blood and the blood-vessels take the principal share in the inflammatory process, while the tissue of the organ remains passive. The pus and fibrine are derived directly from the blood; it is only the new epithelial cells that are produced from the lung tissue. With few exceptions the blood continues to circulate through all the vessels of the lung so that no part of the organ loses its vitality. When the inflammatory process, therefore, has run its course and the products have been absorbed the lung is left unchanged in its structure.

Etiology.—Lobar pneumonia occurs in nearly all climates, warm as well as cold. In the United States it is even more prevalent in the Southern States than in the Northern. To ascertain the prevalence of the disease in New York city, I have examined the records of the Board of Health for a period of four years, beginning on March 1st, 1871. These records give all the fatal cases of pneumonia occurring during that period. After excluding all the secondary and complicating pneumonias, the whole number of fatal cases for the four years was 7,873. Of these 3,623 were in children under five years old. In persons over five years old the great majority of deaths occurred in March, April, May, November, December, January, and February. January showed the largest number of cases, then February, April, May, and March in order. Comparing the mortality with the daily temperature and the daily range of temperature, it was found that the number of cases of pneumonia increased regularly with the lowness of

the temperature and the extent of its daily range.

There can be no question that in a moderate number of cases of pneumonia the disease is developed within a few hours after exposure to cold and wet, but in many other cases no such exposure can be discovered. There is a difference in different years and in different places as to the frequency and mortality of the disease. Occasionally local epidemics occur in a single building or a single town.

Considerable attention has been directed lately to the question of the character of pneumonia, whether it is a general disease with a characteristic local lesion, or a local lesion attended with constitutional symptoms. It is not necessary for me to lay before you the reasons for these two opinions. It is sufficient to say that the prevailing opinion is that pneumonia is a general disease, while I am still of the belief that it is a local inflammation.

As a rule, children under five years old have broncho-pneumonia; persons between five and fifteen years of age may have either lobar pneumonia or broncho-pneumonia; persons over fifteen years old have lobar pneumonia.

Physical Signs.—In the stage of *congestion* the regular signs are moderate dullness and a subcrepitan râle. As soon as there is pleurisy a crepitan râle is developed.

While in the condition of *red and grey hepatisation*, the inflamed lung gives dullness on percussion, increased vocal fremitus, bronchial voice and breathing.

In the stage of *resolution* the dullness and the vocal fremitus decrease, the bronchial voice and breathing become less and less marked, crepitan, subcrepitan, and coarse râles are heard.

In the stage of *congestion* there may be no dullness nor râles, nothing but a change in the breathing. The respiratory murmur may be feeble, or harsh and exaggerated. Occasionally a bronchitis of the larger tubes is developed at the outset of the disease, and then we hear coarse râles all over both lungs.

In the stages of *red and grey hepatisation* the percussion note, instead of being dull, may be flat, tympanitic, amphoric, or cracked pot. Vocal fremitus, instead of being increased, may be decreased. There may be neither bronchial voice nor breathing.

In the stage of *resolution*, dullness, crepitan râles, and feeble breathing may persist for an unusual length of time.

All the physical signs are apt to be obscure in old persons, and may even be absent altogether.

Rational Symptoms.—The invasion of the disease is in about one-fourth of the cases preceded by an irregular fever with moderate prostration, lasting from one to four days. In the rest of the cases the invasion is sudden. One or more rigors of greater or less severity are the first symptoms of the disease in most cases. (Lebert 92 per cent., Grisolle 80 per cent.) It is customary to reckon the duration of the disease from the time of the initial chill. The temperature rises at once, and usually reaches its maximum by the second or third day. After this it is a continuous fever, with evening exacerbations, until defervescence takes place. Defervescence may take place at any time from the second to the eighteenth day, but in more than half the cases it occurs on the seventh, fifth, eighth, or sixth days (Juergensen). The fever usually begins to subside in the evening, and requires from six to forty-eight hours for its disappearance. After defervescence the temperature may fall for a few hours below the normal. A temperature of from 99° to 104° F. may be called the

normal temperature of lobar pneumonia in adults. Higher temperatures indicate abnormal forms of the disease. If the inflammation extends and involves other parts of the lungs, then the fever is protracted, or returns again after defervescence. In exceptional fatal cases the temperature is below the normal for two or three days before death. Sweating accompanies the fever in a considerable number of the cases. It is often profuse and persistent. In other cases, however, the skin is always hot and dry. Pain is regularly developed within twelve hours after the chill. It is sometimes slight, sometimes severe, sometimes absent. It is referred to the affected side, usually to the region of the nipple. This pain is apparently due to the associated pleurisy. The pulse should be somewhat increased in frequency and of fair strength—about 100. A feeble pulse of over 120 should always excite apprehension, even if the patient is apparently doing well. Slow pulses of 60 to 70 are met with in exceptional cases. The respiration at once becomes rapid, rising to 30 or 50. Not only is the breathing rapid, but it may be labored, especially during the first twenty-four hours of the disease. In some cases the oppression and dyspnoea are at this time very urgent, so much so that the patient feels that he will die unless immediate relief is afforded. Cough is developed within a few hours, moderate in some cases, harassing in others, often absent in old people. With the cough is an expectoration, at first white and mucous, later mixed with blood and pus so as to have a yellowish or reddish color. The sputa regularly consist of two parts, a thin watery fluid and little rounded pellets of more consistent and tenacious mucus. In bad cases the whole sputa may be thin and dark-colored, like prune juice. I have seen in one case an hæmoptysis of about three teaspoonsful of pure blood at the outset of a lobar pneumonia. Cases with nothing but white mucous sputa are not uncommon; and in old persons there is often no expectoration at all. The cheeks are usually flushed. The tongue is coated with a white fur, and in severe cases becomes dry and brown. The appetite is lost, and vomiting may be repeated several times at the beginning of the disease. The urine is diminished in amount, high-colored, and occasionally contains albumen and casts. Cerebral symptoms are present in greater or less degree in most of the cases. A peculiar irritability and restlessness with inability to sleep are very common symptoms. In more severe cases headache, delirium, stupor, and coma are also present. Such cerebral symptoms are especially marked in alcoholic patients, in old persons, and with pneumonia of the upper lobes.

Complications.—Pleurisy with a considerable exudation of serum complicates about 12 per cent. of the cases (Grisolle). It is apt to persist after the resolution of the pneumonia. If it is a purulent pleurisy, the patients usually die. Pericarditis, usually with the production of fibrine without much serum, complicates some cases, especially if both lungs are inflamed. In some cases the only evidence of such a pericarditis is the fact that the patient seems more seriously ill. In other cases the pericardial friction sound is heard, the pulse becomes more rapid and feeble, the blood accumulates in the veins, the breathing is more rapid and labored. Meningitis may be developed sometimes without symptoms, sometimes with severe headache, great restlessness, delirium, contractions of the voluntary muscles, stupor, and coma. Jaundice is observed in a moderate number of cases. It may complicate mild examples of pneumonia without apparently adding anything to the patient's symptoms; or it may appear in the course of a more severe pneumonia and be attended with

more marked cerebral symptoms. The kidneys may become the seat of a moderate degree of parenchymatous nephritis, or they may have been in the condition of chronic diffuse nephritis before the pneumonic attack. In the latter case there may be general convulsions.

The Course of the Disease.—In regular cases, after a few hours or days of irregular fever and prostration, or without any premonitory symptoms, the patient is seized with one or more rigors, followed by a febrile movement. He at once feels seriously ill, may vomit, and complains of oppression and difficulty of breathing. The next day, after a restless night, the patient lies in bed with flushed face, a hot, dry skin, a tongue coated and white, rapid breathing, a temperature of 100° to 103°, a pulse of about 100, and full; there is pain in the affected side of greater or less severity, cough with mucous expectoration, and the physical signs of congestion, or of red hepatisation. All these symptoms continue; the temperature from 100° to 104°; the pulse 90 to 100; the breathing 25 to 40. The physical signs are those of red and grey hepatisation. The sputa have the color and shape characteristic of the disease. On about the seventh day of the disease defervescence takes place. The temperature falls to the normal, or below it; the pulse and breathing become less rapid; the tongue begins to clean off; the restlessness disappears, and the patient feels quiet and comfortable. The physical signs of resolution continue for a few days, then disappear, and the patient is fairly convalescent.

Cerebral Cases.—In patients addicted to the use of alcohol, in old people, and in cases of pneumonia of the upper lobes, cerebral symptoms are especially marked. Professional and business men are more likely to have cerebral symptoms than are mechanics and laborers. In many of these cases the extent of lung inflamed is small in proportion to the severity of the symptoms. Besides the restlessness, sleeplessness, headache, stupor, delirium, and coma which characterize these cases, there are usually a high temperature, a rapid and feeble pulse, and a dry tongue. Delirium and stupor may persist for several days after defervescence.

In irregular cases the physical signs of consolidation may be slow in appearing. You may examine a patient's chest day after day and find no evidence of solidification of the lung. The longest delay of this kind which I have seen was for eight days. Resolution may be delayed for two or three weeks after defervescence, with persistence of the physical signs of consolidation.

The Pneumonia of Old People.—In people over seventy years old the disease is apt to run an irregular course. The chill, the pain, the cough, the sputa, and the physical signs may all be absent. Fever, cerebral symptoms, a rapid and feeble pulse, rapid breathing, and marked prostration may be the only symptoms. I have seen such an irregular course of the disease in persons not over fifty years old. There are also curious cases reported of pneumonia in old persons, who only seem feeble but are not confined to bed. They present no symptoms to excite suspicion until they suddenly die, and the pneumonia is discovered at the autopsy.

Typhoid Pneumonia occurs usually in epidemics. The cases are characterized by the severity of the constitutional symptoms and the rapid prostration.

Complicated Cases.—Meningitis, pericarditis, pleurisy with effusion, cardiac disease, and chronic renal disease all may alter the regular course of the disease in ways which have been already described.

The Fatal Cases of Pneumonia.—Pneumonia seems to prove fatal in several different ways. There are

cases in which death seems to be directly due to the large area of lung tissue, which is infiltrated with inflammatory products and rendered incapable of performing its natural functions. There are cases in which only a part of one lobe is affected, and yet the constitutional symptoms are very marked and seem to destroy life by their severity. Death is due to one of the complicating lesions: meningitis, pleurisy, pericarditis, cardiac disease, chronic renal disease. A certain number of cases of lobar pneumonia die suddenly. In some this sudden death seems to be due to interference with respiration. The patients are suddenly attacked with rapid and difficult breathing and die in from half an hour to a few hours. In these cases we often find after death congestion and cedema of the uninfamed portions of lung. Other cases seem to die from failure of the heart's action. In severe pneumonia the heart's action is often rapid and feeble, and it may at any time become so feeble that death takes place suddenly. But even in comparatively mild cases of the disease death may take place in the same way. The disease will run its ordinary course for several days, often for a week, then the heart will suddenly begin to act very feebly, the skin becomes cold, the patient passes into a sort of collapse and dies, sometimes in a few minutes, sometimes after several hours. In rare cases death may take place during convalescence from thrombosis of the coronary arteries.

Duration.—The constitutional symptoms last until defervescence takes place—that is, from the second to the eighteenth day. Resolution follows at any time from two to twenty days later. The fatal cases may die at any time from five hours to three weeks after the initial chill. In New York most of the adults die on the seventh, eighth, and tenth days; most of the persons over seventy on the fifth, sixth, and seventh days.

Prognosis.—The prognosis depends on the extent of lung involved in the inflammatory process; on the existence of complications; on the age of the patient (persons over seventy years of age seldom recover); on the social condition of the patient. Laborers and mechanics are more apt to recover than professional and business men. The prognosis is always much worse in patients addicted to the use of alcohol.

Treatment.—The treatment of lobar pneumonia calls for the exercise of much knowledge and judgment on the part of the physician. It is necessary to be practically acquainted with the course of the disease, and to appreciate fully the exact condition of each patient. There is no routine treatment for pneumonia; each case must be managed on its own merits. If we see a patient during the first twelve hours of a pneumonia the question presents itself as to whether we shall try to abort the disease. This may be done in two ways: by general bloodletting, or by large doses of calomel. The latter plan is the one more frequently employed in New York. From twelve to twenty grains of calomel are placed on the patient's tongue, and this dose may be repeated in six hours. In favorable cases either the bloodletting or the calomel may cause defervescence to take place within a few hours. But both these plans fail in more cases than they succeed. Ordinarily no such attempt is made to abort the disease. Our first care is to put the patient into a condition of absolute rest. He is to be kept in bed, fed on fluid food, and given opium in small doses. Everything which can annoy or irritate the patient is to be strictly avoided. If the temperature runs between 100° and 104° it requires no treatment. If it rises higher than this we may sponge the skin with alcohol and water, give diaphoretics, and aconite or veratrum viride in small doses. Large doses of quinine, cold baths,

and cold affusions not only make no permanent reduction in the temperature, but they are positively dangerous. The pulse should regularly be between 100 and 120. If it is above 120 and feeble, we should endeavor to render the heart's action slower and stronger. The most efficient agent for this purpose is alcohol. Either wines, whisky, or brandy can be prescribed. The amount of alcohol used is to be regulated by its effect on the pulse. It is often well to combine with it either opium or the liquid extract of convallaria. This seems to be the only indication for the use of alcohol in lobar pneumonia. Unless it is required as a cardiac stimulant, the patient is better without it. If the breathing is not only rapid but oppressed at the onset of the disease, the patient may often be relieved by the use of wet cups, dry cups, warm fomentations, or mustard plasters over the whole of the chest. If such oppression continues through the disease, it may be mitigated by the use of calomel and opium in small doses, by aconite and veratrum viride, and by diaphoretics. For the pain in the side, the restlessness, and the sleeplessness, the most efficient remedy is opium, selecting the preparation and the dose to suit each patient.

From what has been said, you will infer that many cases of pneumonia require no treatment but rest and opium; and this is true. If the disease is running a mild and regular course, you are not likely to improve matters by interference. The only indications for treatment are to relieve an abnormal development of any of the symptoms which may threaten to disturb the patient.

CASES OF NASAL POLYPUS PROJECTING INTO THE NASO-PHARYNX; WITH REMARKS.

By E. CRESSWELL BABER, M.B. Lond.,

Surgeon to the Brighton and Sussex Throat and Ear Dispensary.

THE following cases present several points of interest both as regards diagnosis and treatment.

CASE 1. Aural Polyp on both Sides; Removal. Right Nostril: Small Polypus removed from the Front with Forceps. Left Nostril: Much narrowed, preventing view from the Front, but Polypus seen projecting into the Naso-Pharynx by Posterior Rhinoscopy; Removal with Cold Wire Snare.—E. S., female, aged thirty-two, was admitted a patient at the Throat and Ear Dispensary on May 30th, 1879, suffering from deafness, vertigo, and discharge from the ears. She had all her life been subject to an offensive discharge from the nose, with hard pieces coming away. Both auditory canals were occluded by large polypi. These were removed in the usual manner, leaving perforations in the tympanic membranes, and intermittent purulent discharge from the tympana. After treatment of the ears, attention was directed to the nasal cavities, and a small polypus was seen by anterior rhinoscopy in the right nostril. On July 30th it was removed by the somewhat unscientific method of avulsion with forceps, a proceeding which, by the way, I do not recommend. A polypus was also seen in the left nostril by anterior rhinoscopy, but owing to extreme narrowness of the nasal cavity on that side attempts to remove it were unsuccessful, only a piece being removed with the snare on Sept. 21st. On Nov. 28th by posterior rhinoscopy, with reflected sunlight, a glimpse of a polypus projecting through the left choana was obtained, and it could also be felt by palpation. The patient was ordered insufflations of tannin, and remained away a few weeks, being readmitted on

Jan. 19th, 1880. Careful examination then showed a polypus of considerable size nearly filling the left choana, and projecting into the naso-pharynx. Voltolini's palate-hook was employed, but produced so much irritation that it could not be borne. The left nostril was so narrowed by deflection of the septum that the polypus could not be seen from the front, although a soft mass was felt with the probe, from which two small portions were removed with the cold wire snare. On Jan. 28th the polypus was removed in the following manner. The author's self-retaining nasal speculum¹ having been adjusted to the left nostril, a large loop of steel wire attached to an ordinary nasal polypus snare was introduced through the anterior nares along the side of the septum until it reached the posterior pharyngeal wall. By means of the left forefinger inserted in the naso-pharynx, the loop of wire (which expanded by its own elasticity) was then pushed round the growth. The wires were tightened by an assistant until the point of the instrument almost touched the polypus, and the growth was then easily cut off by drawing the loop home. Owing to its size, however, the polypus could not escape through the nostril, but had to be pushed back into the naso-pharynx with a probe, being then ejected through the mouth. The day following, both superior and middle turbinated bones on the left side could be plainly seen on posterior rhinoscopy, but no sign of the polypus was visible. The left nostril was so clear that when the patient was discharged, five days after the operation, the movement of the palatal muscles on deglutition on the left side could be seen by anterior rhinoscopy, which affords, I find, a fair test of the permeability of the lower part of the nasal cavity. Ten months later, examination showed no return of the growth.

CASE 2. Nasal Polypus on left Side projecting into Naso-Pharynx; Removed with Cold Wire Snare. Right Nostril: Small Polypus removed from Front of Middle Turbinal. Also small Eredile Growth on Right Side of Septum, near Posterior Nares, removed with Snare. Use of Voltolini's Palate-hook.—This case is very similar to the preceding. E. Y—, nurse, aged forty-eight, was admitted to the Dispensary on April 3rd, 1880, with the following history:—Last September she first noticed an irritation in the left side of the nose, since which the left nostril has been stopped up and has discharged. She also has a feeling of something falling down her throat from the nose, especially at night. It keeps her awake, and produces great dryness of the throat. Since her nose has been affected she has also suffered from palpitation of the heart. On being asked, she denied that she suffered from asthma, but it appeared subsequently that she suffered from a feeling of tightness in the chest, produced by the polypus. An examination of the nose on the ensuing days revealed the following state of parts: By anterior rhinoscopy the upper part of the left nostril was seen occupied by a polypous mass. Posterior rhinoscopy was extremely difficult on account of close proximity of the velum to the posterior pharyngeal wall. It was just possible, however, to see the upper part of a polypus in the left choana. (Voltolini's hook produced too much irritation to allow of its being employed.) On palpation a firm round swelling could be felt hanging down into the naso-pharynx in that situation. On April 10th this polypus was removed in precisely similar

manner to that in the preceding case, the self-retaining speculum being employed, and the tumour being, as before, expelled through the mouth. Powdered tannin was ordered to be blown into the nostril, and six days after the operation the left nasal cavity was so clear that the movements of the palatal muscles on deglutition could be discerned through the anterior nares. On the day following this (April 17th) the left superior turbinated bone and Eustachian orifice could be seen with the rhinoscopic mirror. At that date also the small polypus attached to the upper part of the left middle turbinal was removed with the cold wire snare from the front. A slight attack of catarrh of the left tympanum then occurred, after which she was discharged. In the following June the patient was again seen, and complained of much discharge from, and soreness in, the left nostril. Various remedies were employed to relieve this—viz., the application of the flat burner of the galvano-cautery to the nasal mucous membrane; syringing with solution of lead through the anterior nares; spray of sulphate of zinc (which, as usual, caused temporary loss of smell and taste), etc. Solutions of perchloride of iron and nitrate of silver were also applied to the naso-pharynx, where it was thought that the root of the polypus could be seen and felt. These were all of little or no avail in arresting the discharge; but great benefit was derived from the use of a spray of equal parts of rectified spirit and water through the anterior nasal orifice. Although the left nostril was thus progressing favorably, and was apparently quite pervious, the patient still complained that she was unable to breathe through the nose at night when lying down. Anxious not to dismiss the case in this state, I again tried Voltolini's palate-hook, and by means of it was able to obtain a very good view of the posterior nares. On the left side the nostril was pervious; there was no sign of the polypus and the Eustachian orifice was visible. On the right side, attached to the septum nasi and projecting into the nostril, was a small rounded swelling of about the size and shape of a split pea. The phenomenon that on assuming the recumbent position for a few minutes, the right side of the nose became obstructed while the left remained pervious could therefore be explained by the little growth, which was probably to a certain extent erectile, becoming swollen and occluding the nostril. It could not be felt with the finger in the naso-pharynx, being apparently just inside the nostril. After the patient had been lying down a few minutes it was removed, on August 2nd, with the cold wire snare, through the anterior nasal orifice, with the left forefinger in the naso-pharynx. There was considerable hæmorrhage afterwards. Four days later she reported that the right nostril was much freer, and that she could sleep with her mouth shut, with consequent relief to the previous dryness of the throat. The complete removal of the little growth was confirmed by the rhinoscope. Three weeks later this good result continued, and both nostrils appeared quite free. It may be noted that at this date the application of the palate-hook was less well borne than three weeks previously.

Quite recently (April, 1882) this patient has come under treatment again, complaining of discharge from and irritation in the left nostril, due to a small gelatinous swelling near the front part of the left middle turbinal, which was relieved by snaring off a small piece, and by the application of the galvanic cautery. Palpation (May 3rd, 1882) showed no trace of the polypus in the naso-pharynx.

CASE 3. Large Nasal Polypus, projecting below the

¹ Dr. A. Hartmann, referring to this instrument (Archives of Otolaryngology, March, 1882, p. 85), says that with it it is impossible to press the tip of the nose upwards. He cannot have tried it, or would find that, by applying the band *obliquely* in the manner figured in the British Medical Journal, the tip of the nose is easily raised by means of the double-curved hook.

Soft Palate and arising from the Left posterior Naris; Removal with Cold Wire Snare.—More recently (Nov. 19th, 1881), I have had an opportunity of removing with my friend Dr. Mackey, a similarly situated polypus. In this case (that of a young woman) the polypus hung down below the velum, and palpation showed that it arose from the left posterior naris. It was removed by a wire loop passed through the left nostril in precisely similar manner to the preceding ones, my self-retaining nasal speculum being employed as before. After removal the polypus measured nearly two inches in length, and about one inch from side to side, being flattened antero-posteriorly. It was attached by a narrow pedicle. A few days afterwards, when I saw the patient, the left nostril was pervious.

Remarks.—The interest of the first two cases centres in the hidden position of the polypi owing to the narrowing of the nasal passages. They indicate what is, of course, well-known to specialists—viz., the importance of a careful examination of the naso-pharynx in all cases of obstruction of the nostrils, without which these two patients would undoubtedly have gone unrelieved. For this purpose both palpation and posterior rhinoscopy stood me in good stead in these cases. In the first patient a good rhinoscopic view of the tumour could be obtained without Voltolini's palate-hook,² the application of which instrument produced too much irritation to allow of its being of any service. In Case 2 the hook was also very badly borne at first, but subsequently, after the naso-pharynx had been manipulated with the finger and repeatedly touched with astringent solutions, it was well borne, and was of considerable service in giving a view of the posterior nares, not only showing the clearness of the left naris (after removal of the polypus), but also the presence of the small vascular growth on the septum, causing obstruction of the right nostril. The conclusion, in fact, at which I have arrived from the use of the instrument in a considerable number of cases is the following. I have found that the application of the hook usually produces so much irritation that in ordinary cases where there is a fair space between the velum and the posterior pharyngeal wall, a better view can be obtained without it, and one quite sufficient for general purposes. Where it is of value is, I think, in cases such as the second one just described, in which the space between the velum and the posterior pharyngeal wall is so small ("Rachenenge") that without the hook no satisfactory view can be obtained. In these latter cases it is worth while to accustom the patient to the hook, in order that the soft palate may be drawn forwards and the parts thoroughly inspected. The concurrence in Case 1 of aural polypi in both ears, with nasal polypi on both sides, is interesting, and points, it would seem, to a constitutional tendency to the formation of local hyperplasias of the mucous membranes to a "(polypoid diathesis," if I may so term it). The polypi were not carefully examined, but were probably of the ordinary myxomatous or fibro-myxomatous character. The operative treatment was simple enough, and easily carried out, although in the last case, on account of the size of the polypus, there was rather more difficulty in adjusting the loop of wire around it.³ Dr. Daly, of Pittsburg,

who has recently strongly recommended⁴ this method of operating in the naso-pharynx (i.e., by using one index finger in that cavity as a guide), not only adjusts the wire snare by means of a finger in the naso-pharynx, but employs the galvanic cautery in a similar manner, withdrawing the finger of course before the electrode is heated. That some risk, however, attaches to the employment of the galvanic cautery near the Eustachian orifices by this plan is shown by the fact of ear complications ensuing after the application of the cautery in two of Daly's cases. Into the respective merits of the hot and cold snare and the forceps for the removal of nasal polypi I do not propose to enter on the present occasion. As regards after-treatment, it being impossible to reach the roots of these polypi directly, astringents had to be applied to the nasal mucous membrane generally. The good effect of alcohol for arresting the discharge after removal is seen in Case 2. In these cases it probably acts in the same beneficial manner as after the removal of polypi from the ear. I have also found a spray of alcohol of service in chronic nasal catarrh without polypi, and recommend a trial of it in suitable cases, beginning with a mixture of rectified spirits of wine one part and water three parts, and gradually increasing the strength.

Brighton.

THE LESION OF MYO-CARDITIS.

By JAMES GREY GLOVER, M.D.

THE following case is worthy of record because it presents a good instance of a rare lesion in a very pronounced form, and further because of the association of this lesion with, at one stage, very striking anginous symptoms, and finally with sudden death.

Mr. C—, aged fifty, who was the subject of emphysema and occasional attacks of bronchitis, was seized suddenly, on Sept. 15th, at his office, with symptoms thus described to me by Mr. Samuel Lloyd, of High-street, St. Giles's, who was summoned in the emergency. Mr. C— was suffering "from violent sudden pain in the region of the heart, and alarming syncope. It was impossible to properly examine him. The pain extended down the left arm." Under Mr. Lloyd's treatment he recovered so far as to get home in a cab. In my absence from town, he was kindly attended by Dr. Cribb, who describes him as suffering in the following way:—"I found him in bed free from all cardiac or respiratory distress, but complaining of pain across the transverse colon from side to side, saying he thought it was 'wind.' He complained of a feeling of 'depression,' and attributed his sufferings to indigestion from having eaten roast pork. His pulse was regular and quiet, respiration neither difficult nor accelerated, there was no pallor or appearance of syncope; extremities warm. I could detect no abnormal sound over the cardiac region, but any such sound may have been masked by his thick covering of fat. Respiration sounds deficient over both backs, but the percussion was clear. I concluded that he had been subject to asthmatic attacks depending on emphysematous lungs. Whatever the attack at the office

² This instrument is simply a strong steel retractor, of which the portion bent at right angles to the shaft measures about half an inch across and three-quarters of an inch in length. For full description of the same, and its mode of employment, see Voltolini's interesting work, "Die Rhinoskopie und Pharyngoskopie," and edition, 1879.

³ In this case a snare was employed, which has been made for me by Messrs. Wright & Co., of New Bond-street, and which I showed at the London International Congress (Sub-section of Laryngology). The wire is contained in a steel tube (measuring

rather over nine centimetres in length and two millimetres and a half in diameter) and adjustable at any angle to the handle by means of a screw near the ring for the thumb. This snare is chiefly of advantage for the removal of growths from the front of the nostrils, as with reflected light it can easily be adjusted to any visible part of the interior of the nose. I have employed it in a considerable number of cases.

⁴ Archives Laryngology, vol. ii., No. 2.

might have been, of which I got a very imperfect account, it had clearly subsided when I saw him. I prescribed for him a stomachic alkaline mixture and hot applications to the seat of pain.—16th: Had not slept well, and said the pain came on again in early morning and in the same region—viz., across the diaphragm and especially to the right side over the liver. He described himself as much better and wanted to get up; no dyspnoea or cardiac symptoms. Temperature normal. His bowels had not acted, so I ordered him an aperient draught and light diet.—17th: The draught acted well, and he described himself as very much better and free from pain, but excessively weak, wanted to get up, and I believe did so. He still complained of an uneasy feeling across the diaphragm, but more over the liver than the heart, always indicating the right side rather than the left.—18th: Was up when I called and said he was getting all right, appetite returning and tongue cleaning, was in much better spirits and walked round his room showing me his paintings; said he should go to business next day, which I believe he did.—20th: Went to business and declared himself almost as well as usual, but weak from the attack. Had no return of pain or discomfort, nor did he complain of any thoracic trouble whatever. Arranged to call on me and report on 23rd; on that day, I believe, walked one and a half miles to my house. He said he only came to show himself, and thanked me for my attention, but would like to look in again in a week." He had so far improved as to have returned to his office, but on Tuesday, September 26th, not feeling well, and having pain in the chest, he was induced, against his strong inclination to go to his office, to remain at home, have poultices on, and to send for Dr. Cribb. Dr. Cribb, knowing of my return, sent the messenger to me. I saw Mr. C—a little after twelve in his library, and was just beginning to hear from him an account of his illness, when his head fell back in his chair, and his feet forward, and he died in a few minutes. A friend at whose house he called the night before said he looked ill and "altered" and complained of "a pain at the heart," but said he should soon be better.

Post-mortem examination.—The body was found very fat and the muscles well nourished. The cartilages of the ribs were so ossified as to require the use of the saw. There was a good deal of fat about the heart; but no hardening of the coronary arteries. The pericardium contained about an ounce, or less, of fluid. There was an ecchymosis on its inner surface opposite the base of the heart, to the left side in front. There was also a little recent lymph hereabouts. But the marked lesion was on the front of the apex of the heart, affecting, apparently, both the surface and a layer of the substance of this organ. At this spot there was a well-defined roundish patch, less than the size of a five-shilling-piece. It looked badly damaged and on the road to gangrene or sloughing. In color it was dirty red, with a little dirty lymph about it. The great vessels proceeding from the heart contained decolorized clots of fibrin. The opposing spot of the pericardium had a corresponding appearance—ecchymosed and with a little dirty lymph on it, but with no adhesion. The valves were unaffected. The lungs were emphysematous and congested, but everywhere free from consolidation. The liver was hard, and its capsule at parts opaque. The kidneys were similarly affected, and had a few small cysts on their surface.

Remarks.—I shall not attempt to trace the course of pathological processes in this painful case, nor assign their exact significance. The fibrinous clots in the large vessels probably had much share in causing death. Possibly some similar clotting

may have occurred in the nutrient arteries of the heart and so led to the lesions described above, but the coronaries were free from obvious hardness. Possibly, a patient more willing to rest, from the beginning, might have fared differently. The case is interesting in this further respect as one of the gravest heart lesions, with an absence of physical signs thereof.

Highbury.

THE TREATMENT OF POST-PARTUM HÆMORRHAGE.

By ROBERT BARNES, M.D.

THE very instructive communication of Mr. Coates on "Two Cases of Intra-venous Injections of Fluids for Severe Hæmorrhage" cannot fail to arrest the attention of the profession. In my "Obstetric Operations" I have taken especial care to dwell upon this method of restoration, basing greatly upon Dr. Little's treatment of cholera by this method and upon his subsequent experience. The late Dr. Woodman found the blood-globules in a patient who had undergone saline injection unaltered. Mr. Coates now adds the extremely valuable fact that the injection of plain water also has no deleterious effect upon the blood-globules. This experiment then amply proves a proposition laid down in my "Obstetric Operations"—namely, that an argument in favor of saline fluids lies in the fact that "the drained circulatory system labors not alone under the loss of the vivifying element, but also under the purely mechanical difficulty of vacuity. The heart and arteries have nothing to contract upon. Now, the simple injection of ten or twelve ounces of fluid restores, to a certain extent, the dynamic condition of the circulation." That this should be effected by the simple injection of "twenty-two ounces of warm water," as practiced by Mr. Coates, is one of the most interesting physiological and clinical demonstrations with which I am acquainted. Yet I think saline solution is preferable, and a mixture of saline and defibrinated blood recommended in my book would be better still. This method of saline injections has the incontestable advantages of being always available at short notice, of avoiding risk of failure from coagulation, of enabling us to use simple forms of apparatus, and of being in other ways a more simple proceeding." Almost any syringe will do; but it is important to have a good cannula, such a one as is fitted to Aveling's apparatus. This should be carried in the obstetric bag.

I wish to add a word or two of comment upon the use of ferric chloride to arrest hæmorrhage. Mr. Coates used it in both cases successfully. In the first case "manipulation, hypodermic injection of sclerotic acid, cold affusions, ice internally and externally, the intra-uterine injection of hot water, were all resorted to; but these measures failing to produce more than temporary contraction, ten ounces of a solution of perchloride of iron (one in five) were injected into the uterus. The hæmorrhage ceased." Here is evidence in support of the proposition I have so much insisted upon, that when the diastaltic function is suspended, persistence in remedies which act through that function is useless, and may be injurious. All the means enumerated above are of this class, excepting the last, the ferric chloride, which may still act by virtue of its local styptic corrugating power when all other means have failed. The other case gives similar testimony; but Mr. Coates gives expression to a suspicion that an attack of secondary hæmorrhage in the subject of it might be due to

the separation of a slough formed after the use of the iron injection, and says he fails to find this danger "alluded to in the ordinary text-books." I am quite aware that the ordinary text-books are very defective in instruction as to the principles upon which uterine hæmorrhage should be controlled; but in the "Obstetric Operations" the consequences of using caustic ferric chloride are discussed, and the necessary cautions are described. Two instances of the caustic action of iron are referred to. Neither of these was followed by secondary hæmorrhage, and Dr. Lombe Atthill is cited as having "used the solid perchloride successfully." At present, then, the weight of evidence is against the supposition that strong iron solutions may cause secondary hæmorrhage by sloughing. Nevertheless, I wish to repeat that it is not necessary to use caustic solutions. The case is one for styptics. The distinction between caustic and styptic iron solutions is clear. The styptic solution should, however, be strongly styptic. One in ten may be strong enough, but I prefer one in eight.

The first thing to do is to take care that the uterus is free from blood or clots. To ensure this a stream of hot water should first be sent through. This is a last appeal to the diastaltic force. If it check the hæmorrhage, the iron will not be used. But often it will fail; then the iron comes to the rescue as the last resource. About eight ounces should be injected through slowly and gently. I have well weighed the advantage of swabbing, and prefer the method by injecting. With those who see no danger in hæmorrhage, or who urge that it can always be checked by "ordinary means," it is useless to reason. Nor can the dictum that the remedy is worse than the disease command respect. Hæmorrhage kills if not checked. It has often killed when the "ordinary means" have failed. One might as logically contend that to use the forceps is worse than to let a woman die undelivered, heedless of the *medio tutissimus*—that is, obstetrically interpreted, "axis traction,"—because in unskilful hands the forceps may tear through the recto-vaginal septum, or rend the bladder.

Harley-street.

A NEW METHOD OF CATARACT EXTRACTION WITHOUT EXCISION OF THE IRIS.

By Dr. H. GALEZOWSKI.

THE operation for cataract has always occupied the attention of surgeons, and justly so, and many methods, more or less ingenious, have been devised for the extraction of opaque lenses. One of the best of these methods was incontestably the French operation or method of Daviel by flap extraction, which gave numerous excellent results. Unfortunately, however, it not unfrequently happened that the most severe suppurative inflammation supervened even when the operation had been most skilfully performed, necrosis of the cornea and panophthalmitis destroying the eye. In presence of such facts it came to be asked whether a very large corneal flap was not the cause of the suppuration, and whether it would not be remedied by modifying the form of the incision. It was on this account that the old method by flap extraction was replaced by the method of extraction by peripheric linear incision. Our eminent London colleague, Critchett, whose loss is regretted by all, brought forward an operation which bears his name, and which consisted in a peripheric linear incision of the cornea, iridectomy, and extraction of the lens with a large curette. After this came the method of von Graefe, or modified linear ex-

traction, which, as is well known, was very soon tried in every country in the world and accepted as being the best, for it did not give rise to suppurative complications. As far as I am personally concerned, I had adopted this last method, and practiced it with various modifications, till the last four months. For a long time I obtained satisfactory results, but occasionally I had to record cases of panophthalmitis in patients in whom there was not the slightest reason to anticipate any complication. I have for the last two years employed the most rigorous antiseptic precautions, but this has made no difference. Last year I had five cases of panophthalmitis in ninety-three operations, the results of which I communicated to the International Congress held in London. Quite lately another Parisian oculist has recorded seven cases of panophthalmitis in 150 operations, and in several other records of statistics similar data are to be found. What conclusion should one draw from this? That iridectomy as well as the linear peripheric operation do not prevent subsequent inflammatory mischief. This conviction seemed all the more plausible to me when, at the beginning of the present year, I saw a panophthalmitis appear in one of my town patients who was in an excellent state of health, and who had undergone the operation of iridectomy two years previously with a view of facilitating the subsequent operation. I extracted his cataract under the most favorable conditions; the operation went off perfectly well, and strict antiseptic precautions were observed. What then was my astonishment when, within the first twenty-four hours, the symptoms of suppuration of the cornea with consecutive iritis appeared. It is difficult to find an explanation of this occurring notwithstanding the iridectomy, but it became evident to me that iridectomy did not prevent such complications. I then formed the idea of returning to the old French method of flap extraction without iridectomy, but I took care to make a different kind of flap. The results I have obtained seem to me so satisfactory that I have thought it useful to record them, and to show how unjust it was to attribute to the iris all the accidents which supervene after an extraction of the lens.

In making an analysis of the 959 cases of cataract extraction that I have performed since 1874, and of which I have preserved the records, I came to the following important conclusions:—1. That the excision of a portion of the iris does not in any way prevent inflammatory complications subsequent to the extraction of the lens. 2. That it is often the cause of secondary cataract. 3. That sclerotic or sclero-corneal incisions are far more prone to cause subsequent complications than corneal incisions, and that they do not prevent subsequent severe inflammation of the cornea and iris. In presence therefore of failures in my own practice, which could not in any way be foreseen, and taking into consideration the considerable number of failures recorded by De Wecker, Abadie, and others, I determined to modify the operative procedure and to bring it back as near as possible to the old French method, or method of Daviel. The modification I employ refers to the form of the corneal incision; thus instead of having a large flap whose periphery is at all points 2 mm. distant from the sclerotic border, I make my puncture and counterpuncture in the cornea, just where it joins the sclerotic, but I make the summit of my flap 2 mm. distant from the superior sclerotic border. The incision is therefore entirely corneal. By this procedure the resulting flap is broader and not so high as in the old method of Daviel, and the incision is elliptical instead of being spherical, and in consequence coaptation is easier

and cicatrization more rapid. In giving this form to the incision a gain of 2 mm. on each side is obtained, and this allows even the most voluminous cataract to emerge without difficulty. The pupil dilates under the pressure of the lens and allows its free passage and then returns of itself to its former position, or is replaced by the aid of a fine silver stylet. Up to the present time I have performed fifty-six operations by this method, and I have not had any serious subsequent complications.

The following are the details of the operation I now almost exclusively perform:—The patient is placed upon an operating table or bed, and his eyelids separated by my articulated spring speculum. I then seize the conjunctiva just below the cornea with a fixation forceps, and gently draw the eye slightly downwards. I then puncture the transparent cornea just at its junction with the sclerotic with a very narrow-bladed von Graefe's knife, and at a point 3 mm. above the horizontal diameter.* Pushing the point of the knife downwards to the border of the pupil, which has previously been dilated, I press on the capsule, incising it from below upwards, then, slightly withdrawing the knife, I push it into the transverse diameter of the capsule, which I then incise in its entire breadth, after which I make the counterpuncture at the opposite corneal border at a point also 3 mm. above the horizontal diameter. Then inclining the edge of the knife slightly forwards I cut the corneal flap in such a manner that its summit shall be 2 mm. distant from the superior sclerotic margin. This first step in the operation terminated, I remove the fixation forceps and spring speculum, and let the patient rest for a few seconds. I then continue the operation by elevating thoroughly the upper lid with my little finger, which, as well as the curette, presses upon the sclerotic border of the incision whilst the patient looks strongly downwards. With the thumb of my left hand I gently press upon the inferior border of the cornea, and then the lens is seen first to engage in the iris, then in the incision, and, finally, to emerge from the eye.

It frequently occurs that after the lens has emerged the iris returns of itself, and the edges of the incision come into apposition. In other cases the iris protrudes, and must then be replaced in the anterior chamber by a fine silver stylet. If any of the cortical substance of the cataract remains in the pupil, it is removed by a curette, which is introduced several times into the anterior chamber or the pupil. The operation being finished, and the eye being open, I turn the carbolic spray on to the eye, and dress with carbolized cotton-wool, and bandage both eyes. As a rule the coaptation of the wound takes place in twenty-four or forty-eight hours. In one case it did not take place for six days. On three occasions there occurred slight attacks of iritis on the seventh, eighth, or tenth day, which easily yielded to antiphlogistic treatment, and on one occasion severe iritis appeared within the first twenty-four hours, but yielded to douchees by the carbolized spray and to the application of leeches.

I have had two cases of hernia of the iris, both of which occurred on the fifth or sixth day, and in both cases I had to excise the protruded portion. The final results after extraction by this method are relatively superior to those I obtained with iridectomy. This I have had evidence of in two of my patients who underwent the operation for cataract, one twelve months and the other three years ago. In one of these cases one eye was operated on with iridectomy, and the other without. The visual keenness obtained in eyes operated on without iridectomy is superior by one-third or

one-fourth to that obtained when iridectomy is performed. It will be easily understood that an eye with a round pupil is much better protected against excessive light, is less dazzled, and the dispersion of luminous rays is much less. Since my recent experience has demonstrated to me the considerable advantages of cataract extraction without iridectomy, I never touch the iris except in the following exceptional cases:—1. When during the incision of the cornea the iris bulges forward in front of the knife and is wounded. 2. In traumatic cataracts complicated by posterior synechiae. 3. In cases where the lens covered by the iris does not engage in the incision. 4. I excise the iris when I perceive that it has been torn during the passage of a hard and voluminous lens.

Paris.

ON A CASE OF SYPHILITIC OZÆNA FOR WHICH ROUGE'S OPERATION WAS TWICE PERFORMED,

WITH REMARKS ON LAWRENCE'S AND ROUGE'S OPERATIONS.

By R. CLEMENT LUCAS, B.S. Lond., F.R.C.S.,

Senior Assistant Surgeon to, and Demonstrator of Operative and Practical Surgery at, Guy's Hospital.

THE operation for exploring the nasal cavity by raising the upper lip and cartilaginous portion of the nose, for which we are indebted to M. le Docteur Rouge, of Lausanne, does not appear to have been performed many times in this country; and it is perhaps deserving of more attention than has at present been accorded to it. Although M. Rouge's *mémoire*¹ has now been published nine years, I can only find that the operation has been performed by three surgeons in this country—namely, Mr. Warrington Haward,² Mr. Harrison Cripps, and Mr. Holmes.³ It may, however, have been performed by other surgeons who have not recorded their experience. Among those who have practiced it the operation does not meet with unqualified approval by all. Thus M. D'Ambria⁴ speaks of it as dangerous from phlebitis, purulent infection, and incomplete operation; and Mr. Holmes,⁵ after relating how in one of his cases serious danger was caused by the inhalation of blood into the lungs, states that "the surgeon cannot honestly represent to the patient or the friends that the operation is free from grave danger." Still, for my own part, I am inclined to regard the dangers as trivial; and the difficulties occasioned by the passage of blood into the trachea can be avoided by the means presently to be detailed. Indeed, it is a maxim which I endeavor rigidly to apply to myself, though I should be loth to apply it without limit to others, that whenever a patient dies from surgical hemorrhage some blame should attach to the surgeon.

Whether the operation is one so generally applicable as the originator supposed, or whether its usefulness be limited to a few cases, it is certain that in several instances it has proved of immense benefit, and that it will remain as an established operative procedure. It is a very superior operation to that designed and practiced by Lawrence,⁶

which might be considered applicable to similar cases. Lawrence's operation, an account of which appeared eleven years before Rouge's, consisted in dissecting up the nose without the lip. An incision was made on either side of the nose commencing external to the lacrymal sac and carried down to the margin of the ala; the cartilages were next separated from the bones, and the septum was divided; the nose being then raised, the nasal processes of the superior maxillary bones were divided with forceps, and some inveterate polypi that had resisted other treatment were removed. Lawrence's operation may still be the operation most suitable for cases of polypi of great size which distend the side of the nose and cheek. I performed a similar operation to this, but on one side only, in 1876, for a very large malignant polypus which bulged out the side of the nose and cheek and projected through the right nostril of a man aged sixty-five. It enabled me thoroughly to clear out the nasal cavity, but the skin being infiltrated on the side of the nose, I had to remove so much of this that an aperture was left after the operation. It would have been easy to have closed the aperture by a plastic operation had not the age of the patient, and the fact that he was an inmate of a workhouse, rendered it scarcely worth the risk. The man came under observation about a year later with some return of the growth, which was again scraped away without difficulty; but whilst still in the hospital he was seized with frequent vomiting, and died from cancer of the pyloric end of the stomach.

Rouge's operation proved to be of great service in the case to be related, enabling me to remove pieces of bone which were found too large to be extracted through the nostrils; yet I doubt if it ought often to be employed simply as an exploratory operation where the diagnosis is doubtful. In this patient we were able to detect the necrosed bone with a probe, and to determine that it was movable before operating, and in all similar cases where it may be found impossible to extract the decayed bone with forceps through the nostril I would advise that the nasal cavity be opened up by Rouge's method. It is probable that in some other cases of long-standing ozæna, when there are strong grounds, from the profuse and offensive discharge, for believing that there is dead bone, though this may not be detected by the probe, I should be inclined to explore the cavity from beneath the lip. But if the cases were limited to these, it would very much narrow the field of the operation as designed by the originator. On the other hand, I do not regard the operation as a dangerous one, and any difficulty caused by bleeding into the air-passages can be avoided by the means I adopted. Thus, whilst the patient lies on his back the bleeding from the primary incision tends to flow round the gums, and may be stopped by sponges, one being held on either side, between the gum and the cheek. The bleeding through the posterior nares, which at one time threatened trouble, I readily stopped by forcing a large sponge secured by a string into the upper part of the pharynx behind the soft palate. This latter procedure has another advantage, inasmuch as it prevents the patient from expelling the blood and foul secretions from the nasal cavity into the operator's face. In the Lawrence's operation described I adopted a similar precaution, but as I was operating only on the right side, the posterior aperture of that nasal cavity alone was plugged.

For the following particulars I am indebted to Mr. A. H. Dodd, who acted as my clinical clerk:—

CASE 1.—T. A—, aged nineteen, was admitted into Guy's Hospital on Sept. 7th, 1891. His father died in an asylum soon after the birth of the

patient, and his mother, who had been a drinker, died of dropsy three years ago. He has one sister alive, but lame from birth. For some years he was totally blind from inflammation of his eyes, which occurred about the age of nine. He had an operation performed, and has since been able to use the left eye. It is evident that the blindness was due to interstitial corneitis, and the operation was for artificial pupil. The teeth, however, are not characteristic of hereditary syphilis. For about three years he has worked in an oil-cloth manufactory as a tear-boy, and during this time his nose has been growing flat. At the same time he has been suffering from a foul-smelling discharge from the nostrils, and many small fragments of bone have escaped through the posterior nares. Of late he has been compelled to give up work, the discharge being so offensive that the other men employed refused to work with him. The patient is a strong-looking lad, but unintelligent in appearance. His skin is coarse and blotchy. His nose is small, broad and flattened; to such an extent have the nasal bones fallen in that the bridge is practically absent. Inferiorly the septum is deficient in its middle third, so that the two fossæ communicate. At the upper part of the left side a large loose piece of bone can be felt. There is a small hole in the hard palate by which the nose communicates with the mouth, and there is also an ulcer on the soft palate.

On September 9th I operated as follows:—The patient being under the influence of a mixture of alcohol, ether, and chloroform the upper lip was stretched and everted by the fingers of assistants, and an incision was made through the mucous membrane and cellular tissue in the angle between the lip and gum. Considerable bleeding took place as the lip was dissected up, which was checked partly by torsion and partly by sponge pressure. The nostrils being reached in this way the cartilages were next separated from the bones, and the nose and upper lip raised together from the front of the nasal cavity. Much increased space was thus obtained for the removal of bone by forceps, but whilst I was engaged in this a considerable quantity of blood trickled through the posterior nares down the pharynx, and expiratory efforts drove some of this out in the form of spray, to the great discomfort of the operator and lookers-on. All danger from this source was, however, effectually stopped by a sponge, to which a string was attached, being forced up behind the soft palate. Several small fragments of bone and three of larger size were removed by forceps. One of these fragments was almost square, being half an inch on two sides, and five-eighths on two other sides, with a thickness of three-eighths. Another piece was triangular, measuring on its sides half an inch, five-eighths, and three-eighths. A third piece was irregular in outline, and about half an inch in length. Afterwards the lip was replaced, and a pad of lint being placed over it a piece of strapping was carried across to retain it in position. The patient was ordered a mixture containing iodide of potassium and iodide of iron, and his nose was frequently washed out by Thudichum's method. On the 19th, and again on the 27th, of September, small fragments of bone came away from the nose, and the discharge continued offensive.

On October 7th a large loose piece of bone being felt, I succeeded in removing it with forceps through the right nostril, and it proved to be a necrosed turbinated bone. On the 10th more dead bone was detected, but the piece was too large to be extracted through the nostril. One or two attempts were made to remove this piece with forceps, but on each occasion much pain and a good

deal of bleeding were caused without any result. Accordingly on the 18th chloroform was administered, and Rouge's operation again performed. A black offensive piece of bone, an inch and one-eighth by three-quarters of an inch, was extracted, besides three or four smaller fragments. The lip was afterwards strapped down as before. The patient had no rise of temperature after the operation, and left the hospital on the 25th much relieved, and free from the offensive smell.

Finsbury-square, E.C.

ON THE CURE OF ABSCESES ABOUT THE NECK WITHOUT CICATRIX OR OTHER DEFORMITY.¹

By F. J. B. QUENLAN, M.D., M.R.I.A.

EVERYONE has experienced the trouble and difficulty of curing abscesses about the neck, whether strumous or caused by the irritation of a diseased tooth, without deformity. If the abscess be allowed to burst a most disfiguring cicatrix is the result; and the same consequence, too, often attends the most carefully performed incision. Occasionally a very deep incision made with a sharp narrow and pointed knife is successful, but not more so than the plan adopted in the following two cases.

Kathleen D—, aged eighteen, of Rathowen, Co. Westmeath, was admitted into St. Vincent's Hospital at the beginning of the present winter session suffering from a large and painful swelling of the left lower jaw. There was considerable heat and pain on pressure, and the mouth could not be opened. In the centre of the swelling very deep-seated fluctuation could be felt. Spirit lotion was applied on lint until Oct. 5th, when the purulent matter could be felt a little more than half an inch from the surface. A thin curved needle, about three inches in length, was threaded with fine silver wire, mounted on a handle, and passed deeply into the swelling from above downwards so as to admit of drainage. The wire was thus got through the abscess, and the ends were tied together outside the skin. Spirit lotion was now applied on lint and changed three times a day. From the first there was a small quantity of pus on the lint, and this increased every time until in about a week the abscess was entirely drained. A watery discharge now ensued for three days longer, when the edges of the little wounds began to pucker in. The wire was now removed, and a compress applied over the site of the abscess, and between the two openings, which shortly afterwards closed up, leaving two cicatrices, each about the size of the head of a large pin. These cicatrices were at first red, but gradually became white. She was now able to open her mouth, and it was found that the diseased stumps of the second bicuspid and first two molars remained in the alveoli. These were removed, and she shortly afterwards returned home, all swelling gone and with no appearance of the disease, except the two minute cicatrices already mentioned. She is now in excellent health.

Annie D—, aged thirteen, a pupil in a large boarding school, was shown to me on Dec. 5th, 1881, with a swelling under the jaw, the result of a diseased tooth. It was in a much earlier stage than the former case, and, while fearing it was too late, I ordered three leeches to be applied, the bites to be allowed to bleed as long as they would, but no stuping or poulticing. When the bleeding

was over I directed mercurial ointment to be gently rubbed in with the point of the finger three times a day. This was, of course, for the purpose of producing resolution, and might have succeeded. Unfortunately the mother of the child, who had a great prejudice against mercury in any shape, prevented the latter part of the treatment, and, as a result, suppuration occurred. The same plan was adopted, the matter being got at a good deal deeper. The result was perfectly successful, and I mention the case because, shortly before last Christmas, I was shown the same patient suffering from a slight attack of bronchitis. Curiously enough, it was on the anniversary of the former operation, and I was positively unable to tell by ordinary external inspection on which side the abscess had been. She pointed out the spot, and I could then see with a lens the two cicatrices, reduced by contraction, to minute white points. The offending tooth had, of course, been extracted at the time of the operation, shortly after the removal of the silver wire.

The great point in this procedure is to introduce the little silver seton immediately after suppuration has commenced, and while the matter is still at least half an inch from the external surface. If it be allowed to come nearer, absorption of the areolar tissue will occur, and will leave a hollow over the site of the abscess. Nearer still, the true skin may be injured, and then there will be, in addition to the hollow, a red mark, which will last for a long time. If the seton be introduced exactly as in these two cases, there will be practically no mark whatever. The needle is best introduced mounted on a temporary handle, like that which holds the mirror of a laryngoscope. If held in the fingers it is hard to get the necessary depth. In the case of D— the abscess was exactly over the facial artery; but there would have been no danger in introducing the needle double the depth, for the amount of plasmic matter effused lifted the part well away from that vessel. From first to last there must be neither poulticing nor stuping. This method has never failed in my hands, and I could give other cases, but they would be mere repetitions. Miss D— was the first instance in which I used it, and I merely mention her case to show the satisfactory state of things a twelvemonth afterwards. One of my other cases was done with strict antiseptic precautions, but, as far as I could see, without any corresponding benefit.

Dublin.

EPIDEMIC OF HERPETIC FEVER.

By G. H. SAVAGE, M.D. Lond., etc.

I PROPOSE in this note reporting briefly an epidemic which invaded King Edward Schools, Bridewell (Hospital), Witley, Surrey. I may premise by saying that this resembles the disease described by Trousseau as herpes of the pharynx, but seems to have been unusually severe in its nature. I shall be glad to know if any similar epidemics have occurred in other parts of England. Between Nov. 13th and Nov. 27th, 1882, thirty-nine boys were affected, but only nine cases were complete—i.e.—had all the symptoms. The general nature of a case was as follows: A boy would rise in the morning somewhat languid, and suffering from headache. He would have little or no appetite for breakfast, and complained of cold; in an hour or two he would shiver, and later vomit; the vomiting generally passed off after one severe attack and did not recur; the bowels were never loose, generally natural or confined. Little or no solid food would be taken during the day, and the temperature would be found to be high—from 102° to 104·8° F. There was great thirst, and the face became

¹ Abstract of a clinical lecture delivered in St. Vincent's Hospital, Dublin. Illustrated by two cases.

flushed. At night the restless tossing or even active delirium; in the morning the temperature would be rather lower than at night, and there would be signs of herpes about the lips or lobes of the ears. These herpetic patches consisted of several vesicles aggregated into a patch, and there were often several of these patches. In two cases there occurred scattered vesicles on the inferior extremities. About the same time the patient complained of sore-throat, and this was found to be swollen slightly, red, but not having the appearance of a scarlet fever throat, the tongue was moist with some white fur, the appetite remained bad during the second day, and the temperature slowly fell, rising sometimes on the second night again. On the third morning the herpetic patches had matured, and the throat either presented a dull red oedematous appearance or else exhibited one or two small spots, probably herpetic, the tongue was cleaner, and in only one case did I see any prominent red papillae at and near the tip. By the fourth day the temperature was normal, the patient convalescent. No cases relapsed, and none had complications. There were no evidences of lung inflammation. No local causes could be discovered, for though at first nearly all the cases appeared in one large block, all the later ones were in a new building. No similar epidemic was present in the neighborhood, and though the urinals had not been well flushed I could not trace any direct connection between bad drainage and the origin of the epidemic. Another point of interest in the epidemic was the fact that those attending on the boys suffered more or less from a similar disorder. Thus our chaplain writes to say that his daughter, who tended the cases, suffered, and also two of his servants, who were not brought into contact with the boys, but with the lady nurse only; besides these several other members of the training staff and their families suffered. In these milder cases, shivering, pains in the head and the stomach, sore-throat, and rise in temperature, and in nine herpes of lips, made up the symptoms. Great prostration followed in all cases. Albumen was not found in the cases examined for it, but I suspect that there being no resident medical man the urine was not examined constantly.

Bethlem Hospital, St. George's-road, S.E.

ON A CASE OF DAMAGE TO THE HEART FROM THE INHALATION OF NITROUS OXIDE.

By WALTER OTTLEY, M.B., F.R.C.S.

IN THE LANCET, in 1876, Mr. Cartwright makes some important observations on some of the serious consequences which may follow the inhalation of nitrous oxide, particularly with reference to the effect of repeated inhalations on a heart whose walls are already weak, though its valves may be competent. I have lately met with a case which appears of considerable importance, as showing the effect that several inhalations of gas may have on a heart whose valves have been affected without there being much consequent affection of the walls.

Miss F. O—, aged twenty, had her first well-marked attack of rheumatic fever in July, 1876. After it had lasted more than three weeks the fever recurred, and it was during this attack that endocarditis was first set up; a mitral murmur of considerable intensity remained after her recovery. In January of the following year she had a second attack of acute rheumatism, which passed off, leaving the murmur in much the same

condition; but, as she continued to have rheumatic pains and a good deal of palpitation and dyspnoea, she was sent to Bath, where, under Dr. Spender's advice, she derived much benefit from the baths and other treatment, "the heart became stronger and the murmur less intense," as he has been kind enough to inform me. A second visit in the following year was also attended with benefit, and my partner, Mr. Bartlett, under whose care she had been all this time, found that on her return the mitral murmur was no longer audible. On Oct. 7th, 1882, I was asked to examine her heart in order to decide whether she might safely inhale nitrous oxide preparatory to having some teeth drawn; and as at this time no murmur was audible, and her heart, though somewhat enlarged, appeared in good condition, I had no hesitation in advising her to have the operation performed under nitrous oxide. Accordingly on October 17th she had two teeth extracted while under the influence of the gas, and again two on the 21st, when evidently something did not go quite right. The administration had to be interrupted. The patient felt some pain at the time, and complained afterwards of violent headache and a feeling of confusion, though after the first administration she had recovered quickly. She experienced palpitation in bed two nights after this. A few days later she returned home from the town where the teeth had been extracted, and on October 28th I was asked to examine her chest, as she had been coughing a good deal, and had further attacks of palpitation, and to my surprise found that a loud mitral murmur was again present, conducted towards the left, though not audible at the angle of the scapula; the apex beat was in the nipple line, where it had been before.

I should add that in this patient the murmur has the peculiarity of being very much louder in the recumbent than in the erect position. This to some extent may explain the apparent disappearance of the murmur previously to the administration of the nitrous oxide, as she was only examined by me while sitting up; but I have no doubt that this does not account for all the difference that is now perceptible, for at present not only is a distinct systolic apex murmur audible whilst she is standing, but also she complains that her palpitations and shortness of breath have returned much as before. It appears to me therefore quite clear that the nitrous oxide must be held to be responsible for her present condition; and I have advised her for the future to submit to the pain of extraction rather than to run the risk of further damage by inhaling any anæsthetic.

Ladbroke-grove, W.

ON A CASE OF SPINA BIFIDA SUCCESSFULLY TREATED BY INJECTION.

By E. MUIRHEAD LITTLE, M.R.C.S. Eng., etc.,
Out-patient Surgeon to the National Orthopædic Hospital.

M. E—, aged three weeks, was brought to the hospital last May suffering from spina bifida. The child was well nourished but somewhat pale. There was a large sac in the lumbar region, the bone deficiency extending from the second lumbar to about the second sacral vertebra, the tumour being three inches in diameter, nearly circular, and standing out fully one inch from the body. It rather overlapped the edges of the fissure and was very tense. Its walls were very thin, membranous, and transparent, and on its summit was an ulcerated surface as large as a halfpenny. The tumour appeared in no way affected by the child's crying or inspiring. Both lower extremities were

affected with talipes varus of the usual pronounced congenital type. The mother stated that the tumour was increasing, and that the child moved its lower limbs very little. She readily consented to an operation as affording a chance of cure. The patient was admitted on June 1st, and by the courtesy of my colleague, Mr. F. R. Fisher, I retained the care of the case. The following notes will speak for themselves:—

June 1st: The sac was aspirated, and six drachms of clear fluid removed; remains about three-fourths full. No ill effects followed.—3rd: The sac refilled; it was again aspirated and one ounce and a half of fluid removed.—6th: The patient is very unwell. Starts at slight stimuli. Does not sleep, but cries continually.—14th: Is again in usual health, sac aspirated and six drachms removed. No ill effects.—21st: Sac refilled. Half emptied and twenty minims of Morton's iodo-glycerine solution injected.—22nd: No bad symptoms.—23rd: To be out-patient.—27th: Sac much smaller, its walls thicker and redder. The sore has healed.—28th: Tumour has not shrunk for the last day or two; half a drachm of solution injected and collodion freely applied. From this date the tumour rapidly shrank, until the skin over the fissure was level with the rest of the back. The treatment of the talipes has since been proceeded with, and the necessary tenotomies, etc., have produced no bad effects. Simple evacuation of fluid was first tried as recommended by Dr. Morton. It would, perhaps, have been as well to have proceeded to inject at first.

CASES SUGGESTIVE OF A PROBABLY PROLONGED INFECTIOUSNESS IN SOME CONVALESCENTS FROM SCARLET FEVER.¹

By J. SPOTTISWOODE CAMERON, M.D., B.Sc. Edin.,

Hon. Physician to the Huddersfield Infirmary; Medical Officer of Health and Physician to the Borough Fever Hospital, Huddersfield.

THE question how long the poison of scarlet fever may remain about the person of a patient, convalescent from the disease, is at once so important and so difficult to answer, that I shall perhaps be pardoned, as the following cases are somewhat suggestive, for giving such particulars of them as have either come under my own observation, been furnished me for the purpose by my friend Dr. Stuart, or gathered from the relatives of the patient.

On Tuesday, Feb. 14th of the present year, Ada, the eldest child at home of George B—, a journeyman mason, was seized with vomiting, and complained of a sore-throat. On Wednesday the skin of the chest was covered with "small brown dots," the face was flushed, and the child was feverish. The mother attached no great importance to the symptoms, as the child was delicate and often ailing. She kept her, however, in bed, but next day (Thursday) during her mother's absence, the girl got out of bed and went to the outer door. She would appear to have thus got a chill, for the red-den or rash on the skin disappeared, and on the following Monday the mother noticed a slight swelling or puffiness of the face. There was also swelling of the hands and ankles, and these symptoms so alarmed the girl's mother that next day she asked Dr. Stewart to see the child. This he did on Tuesday, Feb. 21st. Feeling in some doubt as to whether the child might not have had a slight attack of scarlet fever, Dr. Stewart advised that the two other children should be sent away. They

were accordingly sent to Mrs. B—'s mother, next door, and remained there, as we shall see, some eight weeks. I am informed that there was no intercommunication between the houses, but I do not ask any one to accept that literally. The arrangement, however, was probably as efficient, or as inefficient, as the separation of a scarlet fever patient in one room of a moderate-sized house generally is.

The patient was under medical care till March 13th, and was, her mother says, in bed about a fortnight of that time, but loose skin peeled off for some time longer. Later, I cannot learn exactly when, but not till risk of infection was supposed to be over, the house was cleaned down, white-washed, the paint and furniture washed, the mother's and children's dresses and underclothes, the bedclothes, bedticking, even the flocks of the bed itself, washed, while flannels, old blankets, and some other things of little value, and which could not be washed, were burned. The mother's bonnets had never been out of their box, and that, for want of room, had been all the time at the grandmother's. I do not find that Mr. B—'s clothes were subjected to any process of disinfection. Otherwise disinfection was carried out as completely as, perhaps even more thoroughly than, is usually done by people of the same class, and on March 23rd, rather more than five weeks from the date of attack, the father, mother, and convalescent moved to another cottage about a quarter of a mile distant. Rather more than three weeks after, when they had got thoroughly established, the two younger children were brought to the new home. This happened on Sunday, April 16th, nearly nine weeks from the commencement of the patient's illness.

The second girl, Florence, a child of four, slept with Ada that night, and next (Monday) morning was sick, vomited, and complained of sore-throat. On Tuesday she had a rash, more distinctly marked than ever Ada had, and Mr. B—'s mother, who came in, suspected scarlet fever, and advised them to get the doctor. Dr. Stewart's assistant saw the child on the 20th; he saw her himself on the 21st, and informed me of the case on the 22nd, requesting that; as the mother was expecting to be confined, I would take steps in the matter. I saw the children at once, and felt inclined to call both cases scarlet fever. There was a certain amount of roughness of the skin still about Ada, hardly typical desquamation. The younger child had a slightly dusky ring round the isthmus of the fauces, but no very distinct rash. I explained to the father the state of the case—that I could not say more than that probably both children had had scarlet fever, and offered, if he was willing to run the risk, to send them to the scarlet fever ward at the borough hospital, but gave him the alternative of sending them both to some friend who had no children, and who did not intend to be with his wife during her confinement. I gave him an hour to make up his mind, and he elected to send the children to his wife's sister, a married woman without family. They were sent to Mrs. R—'s, about half a mile away, at once, and the house emptied of people and well stoved with brimstone by one of our inspectors. Mrs. B— had a slight sore throat at the time the children were sent away. That night Mrs. R— took the second child, Florence, into her own bed, and next morning (Sunday, April 23rd) she was sick, had a sore-throat, and the following day a red rash. When I saw her, a few days later, she was suffering from a well-marked attack of scarlet fever. The children remained there till after their mother was confined, and till after Mrs. R— herself had quite recovered. Mrs. B— was confined on May 23rd, and did well.

¹ A paper read before the Huddersfield Medical Society Nov. 7th, 1882.

When Dr. Stewart considered the cases ready for disinfection, the corporation officials fumigated Mrs. R——'s house, removed for disinfection the bedding, bedclothes, and clothes, and some eleven weeks from the time they had been sent away the children returned home. A few days later the third child, a boy of twenty months, was attacked in a similar way. His mother brought him, as an out-patient, to my clinic at the infirmary on October 31st. He has never been thoroughly strong since his illness in the summer, and has a trace of albumen in his urine.

The points of special interest about these cases are—(1) That a child, nearly nine weeks after the commencement of her own illness, should apparently have conveyed the poison of scarlet fever to her sister by contact; and (2) that an ailment so little marked, that one hesitated to incur the risk of sending the children to the fever hospital, should apparently have been infectious enough to cause a well-marked attack of scarlet fever in a healthy adult, who, as we learned afterwards, had not previously had the disease.

The amount of scarlet fever in the borough at the time was below the average of the same season during the three previous years. From the middle of April, for six weeks, it was as nearly absent as this disease ever is from a large town.

My own feeling about the infectiousness of scarlet fever at present is, that it is unwise to allow children to mix with others till desquamation has quite ceased, and my experience, during the last few years, of close upon a thousand cases of this disease at the borough hospital, is that the process is seldom completed before the eighth week, is often incomplete at the tenth, eleventh, and even the twelfth week, and is by no means always ended at the thirteenth week.

Huddersfield.

POSITION AS AN AID TO THE REDUCTION OF IRREDUCIBLE HERNIÆ.

By BUXTON SHILLITON, F.R.C.S.,
Surgeon to the Lock Hospital.

THE following case is, I think, of sufficient interest to justify its record.

I was consulted in June last by a rather stout active lady, aged forty-eight years, mother of ten children, for an irreducible left femoral hernia. The hernia had existed for three years. No truss had been worn and no special notice taken of it. For the first year it frequently went back, but for at least eighteen months it had never returned. Recently it had given rise to some pain without any apparent increase in size. On examination I found a very tense roundish swelling, about the size of a large walnut, in the ordinary situation of a femoral hernia. Neither coughing nor change of position appeared to make any alteration in its bulk. I endeavored for a considerable time to reduce it, but without making the smallest impression upon it, and I then sent her home, ordering her to keep perfectly recumbent, to live on low spare diet, and to take repeated doses of a saline purgative. I saw her three days after. She had kept entirely in bed, and had followed my instructions. I again attempted reduction, but without success, and I ordered the same treatment to be continued for another four days, when I again visited her, and again unsuccessfully applied the taxis; it appeared to me to be absolutely irreducible. I then explained to her that I was desirous of trying the effect of position upon the rupture, and that I wished her to remain with her head downwards some few minutes two or three times a

day. She entered fully into the plan and agreed to give it a fair trial. I had a mattress placed on the floor, and I got her to slip off the side of the bed so that she rested on her elbows on the mattress, her sister and nurse, standing on the bed holding her up by her legs. The first day she could not bear this position for more than two or three minutes twice in the day; the second day she three times remained for five minutes. On the third day I saw her, and finding no change I recommended that she should support herself sideways on her right shoulder and arm, one attendant supporting her round her waist, another taking the legs, and a third keeping the left side higher than the right, at the same time that with one hand she gently pushed the tumour in an upward direction towards the feet. For the next two days this was tried three times for five minutes at a time. On the third day, on the third trial (which was continued for seven or eight minutes) it yielded, being, as she described it, slowly dragged into its place. A truss was then fitted, and in a few days she was moving about as usual.

APO MORPHIA IN CASES OF POISONING.

By AMAND ROWTH, M.D., B.S., M.R.C.P. Lond.

THOSE liable to be called to cases of poisoning are always glad to have an agent handy which, not in itself lowering, will produce prompt emesis, especially in those cases where the jaws are rigidly clenched and the stomach pump absent or inadmissible. This agent I am sure we have in apomorphia, an alkaloid which Dr. W. Murrell has brought before the profession. Though a derivative of morphia, it has no narcotic effects in the doses required to cause emesis. Dr. Murrell recommends it to be kept in a solution of 1 in 50 strength, and to be given subcutaneously in doses of from 3½ to 10 minims (1.15 to 1.5 grain). Emesis occurs in from two to five minutes, the contents of the stomach being usually voided in one rush without previous nausea, but with violent and visible muscular action of the stomach walls. The following two cases will serve to show its utility.

CASE 1.—I was sent for to see Mrs. S——, who was said to have swallowed a white powder and to be then dead. I found her on the floor, doubled up, jaws and hands clenched, blood and froth at mouth, respiration seemed absent, and pulse barely perceptible. She had not vomited. Though evidently dying, I injected five minims of the above solution into her arm, keeping my hand on the pulse. In two minutes and a half by the watch the stomach evacuated its contents with a rush, whilst the pulse seemed to rally for an instant and then finally ceased. Oxalic acid was proved to have been the poison used, and at the post-mortem about two drachms only of fluid were found in the stomach.

CASE 2.—A lady, a dipsomaniac, had obtained access to the wine-cellar and had swallowed straight off two bottles and a half of brandy. She then put the corks in her pocket, hid the bottles, put on her clothes, and went out for a walk with her footman. She walked quite steadily for 300 yards, when she dropped down insensible, and was carried home in a cab. On arrival, ten minutes after, I found her comatose, not able to be roused, respiration stertorous and infrequent, pupils dilated and insensible, jaws clenched, pulse slow and intermittent, two or three beats in every eight. Her stomach was full of fluid. I injected 3½ drops of the solution, and in exactly three minutes and a

half about a pint of alcoholic liquid was expelled, and altogether in about five minutes a quart (measured) of hardly-altered brandy was vomited. The pulse and respiration now improved, the pupils becoming slightly sensible, and I left her for two hours, by which time she could be roused temporarily. After twelve hours' sleep she awoke none the worse.

Apomorphia fails to cause emesis during chloroform narcotism, but no other drug seems to be antagonistic to it, and there is no reason why it should not be used to get rid of even morphia itself. In the dyspnoea of chronic bronchitis, emesis from apomorphia produces temporary relief. If only the certainty, rapidity, and absolute safety of apomorphia were known, it would undoubtedly form part of every practitioner's paraphernalia.

Upper Montagu-street, W.

NOTE ON A CASE OF RUPTURE OF THE HEART.

By OGILVIE GRANT, M.B., C.M.

A CASE of rupture of the heart, which differs in some respects from Dr. Coupland's case in *THE LANCET*, and in one respect from most recorded cases, came recently under my notice. Dr. Coupland, quoting Dr. Quain, says, "He also points out, what all writers from Morgagni downwards have noticed, that the exciting cause of the rupture is some sudden mental excitement or physical effort." In the case which came under my observation neither of these conditions was present. The case was that of a corpulent woman, about sixty years of age, who had never complained of, and was not known to be suffering from, heart disease. She retired to her room much in her usual health, and next morning was found dead in bed. From the position of her bedroom if she had called out she would have almost certainly been heard. At the autopsy the pericardial sac was found distended with large clots of blood. The heart was hypertrophied, and on the surface there was a large quantity of fat. On the posterior wall of the left ventricle, about two inches from the apex, there was a rent, about an inch in length, through which a finger could be introduced into the cavity of the left ventricle; the sides of the rent were irregular and very friable; the valves were healthy and no atheroma was observable. In this case the age and sex of the patient, and situation of the rupture, agree with most recorded cases. The cause—true fatty degeneration—was determined by microscopical examination, and also agrees with most published cases, but the peculiar feature of the case is the fact that the rupture took place during sleep, when the heart would be supposed to be most free from exciting causes, and thus differs from most recorded cases.

Inverness.

CASE OF FIBROUS PAPILLOMA OF THE FEMALE BLADDER SUCCESSFULLY TREATED BY OPERATION.

By FREDERICK THORNE, M.R.C.S., etc.

ON June 18th, 1881, I received an urgent summons from a lady, aged twenty-eight, and unmarried, who had passed a considerable quantity of dark porter-colored urine. This, upon inquiry, had occurred twice before at intervals of twelve months, but as the general health was not in any way affected no notice was taken of it. On examining the water with the microscope I found, as I

thought, a large quantity of hæmatin, but few blood cells, and imagined the case to be one of hæmatinuria; but as I had to convey the specimen in warm weather a distance of twenty-five miles, I now conclude that this appearance was due to commencing decomposition. The hæmorrhage yielded to internal treatment by astringents, but relapses occurred at intervals of a few weeks until January last. The bleeding then increased in quantity and frequency, and soon became constant, being accompanied by all the distressing symptoms of cystitis. The bladder was examined for stone, failing to find which I proposed to dilate the urethra, if only as a means of diagnosis, on the ground that the symptoms justified a suspicion of the existence of some form of papillary disease. My diagnosis was not supported by others who were consulted, the prevailing opinion being that the case was one of tubercular ulceration of the bladder, and it was decided to use injections. These were continued until May, blood being always present in variable quantity in the urine.

I may here mention that the only injection which had any effect in controlling the hæmorrhage was one containing fifteen grains of alum to the ounce of water. Meanwhile I had become more and more suspicious of the existence of some morbid growth, and was confirmed in my opinion by that of Dr. W. Roberts, to whom I sent some specimens of the urine. On May 24th he wrote to me as follows: "The deposit contains large numbers of round-tailed and spindle-shaped cells, deeply stained with hæmatin. Mingled with these are numbers of red blood discs, mostly of withered appearance, but infinitely few in proportion to the deep coloration of the urine. This point reminds me of the state of the urine in cases of intermittent hæmatinuria. . . . My impression at present is that there exists one or more polypoid growths."

Early in June I found in the urinary deposit a small fleshy particle the size of a small pea, in which, under the microscope, I could distinctly trace bloodvessels. An operation was now sanctioned, and on July 11th, the patient, having been placed under the influence of chloroform, I rapidly dilated the urethra, and found, just within reach of my finger, a large soft mass growing from a pedicle attached to the base of the bladder. Seizing this with forceps, I dragged it, with a portion of the bladder, through the urethra, transfixed the pedicle with two sharp hooks, and separated it with scissors. Some adjacent rough patches were removed with the curette, and the stump was freely swabbed with tincture of iodine, and, all bleeding having ceased, returned into the bladder, which was then injected with iced water, with about 10 per cent. of tincture of iodine. By this means another mass nearly as large as the one removed was washed out, it having probably been detached during my efforts to pull the tumour through the urethra. The size of the entire growth was about that of a tennis-ball. After the operation the patient passed water naturally every four to six hours. The temperature and pulse were normal throughout, and all trace of blood disappeared on the fifth day. She progressed favorably until July 21st, when at 4 A.M. violent hæmorrhage commenced, the bladder evacuating large clots every few minutes. Ice was applied over the lower abdomen, and introduced into the vagina, injections of iced water and tincture of perchloride of iron were used, but no means availed to control the bleeding until gallic acid in doses of forty grains, twice repeated, were administered. The first dose was vomited. I adopted this course, having found it immediately effectual in severe hæmorrhage after extraction of a tooth.

No recurrence of bleeding took place, and with the exception of great exhaustion and some anæmia the patient's recovery from this time was uninterrupted. Mr. Butlin kindly examined a portion of the growth for me, and describes it as "a very good specimen of papilloma with a fibrous basis." "It appears," says he, "to be much larger than is usually the case." I believe this disease is very rarely met with in so young a subject, but I am strongly of opinion that in all obscure cases of hæmaturia in the female rapid dilatation of the urethra as a diagnostic measure should be resorted to. I have never known any permanent inconvenience result from such dilatation, for whatever purpose adopted; and it is evident that if such means had been earlier agreed to in this case my patient would have been saved much misery and suffering, and some considerable risk to life from the repeated and long continued hæmorrhages which occurred.

Leamington.

ON BEDSIDE URINARY TESTS.

By GEO. OLIVER, M.D. Lond., M.R.C.P. Lond.

ALL busy practitioners must admit the clinical utility and importance of accurate, time saving, and portable tests, by which they may, during their rounds, decide with precision and certainty, and on the spot, pathological conditions of the urine, or satisfy themselves, and their patients, if need be, without delay as to the soundness of that excretion. From the numerous contributions on portable urinary tests which have recently appeared in these pages, it is clear that practical men, who have long realized the serious inconvenience of carrying about caustic fluids for testing at the bedside,¹ are anxiously feeling their way to more manageable and handy yet equally trustworthy reagents, and I take it the profession at large is prepared to accept any useful suggestions towards this end. Hence the articles of Dr. Roberts on Acidulated Brine, of Mr. Stephen on the Volumetric Estimation of Albumen, of Dr. G. Johnson on Picric Acid, and of Dr. Pavy. The corrosiveness of nitric acid and the causticity and instability of Fehling's solution, rather than want of faith in the trustworthiness of these tests, have doubtless mainly prompted the suggestion of more portable reagents. In the substitutes we therefore seek for compactness, handiness, and portability, without the sacrifice of the generally admitted reliability of the old forms for clinical purposes. Doubtless others besides myself have been trying to supply this desideratum, and may be prepared to offer useful hints. Having, however, attained to certain results which have satisfied my own clinical needs, I feel I should not delay further in communicating them to those of my professional brethren whom they may interest; and I do so with the hope that they may prove useful, especially in the saving of time to busy men, and may facilitate urinary investigation at the bedside. My experiments have embraced the qualitative and quantitative testing of albumen, sugar, and total acidity. I should make the preliminary statement that I have succeeded in all my reagents in abolishing the fluid state, and likewise the solid form, either of powder, crystal, or pellet. It occurred to me some time ago that evaporation of the test fluids I was then using on chemically inert filtering-paper, linen, or other similar fabric, would secure the deposition of the reagents in a finely divided and concentrated state, a condition it was hoped favorable to such a rapid

re-solution of them in the urine as to produce a quick and sensitive action on the constituents sought for. I soon discovered that my pieces of chemically charged paper were, when dropped into a small quantity of the urine in a test tube, very delicate and cleanly tests; and being in the most portable and compact of all forms for clinical work, and, moreover, affording better results than I had previously obtained from the old corrosive test solutions, it was not long before I cleared my spoilt urinary case of the latter; and I can assure my readers I did so with a feeling of satisfaction and comfort. Then, inasmuch as it was an easy matter to graduate the papers with standard solutions of the reagents, I next proceeded to inquire how far this simple process could be carried in determining the quantities of albumen, sugar, and total acidity; in other words, I thus attempted to apply at the bedside the volumetric method of analysis in the form of pieces of filtering paper charged with definite quantities of the reagents with a quantitative color limitation on paper from which the percentage of the constituent sought for could be at once read of. Up to the present I am satisfied in having attained rapid and, for all practical purposes, sufficiently accurate results. I intend shortly, as a matter of curiosity, to scrutinize the figures indicated by my paper method for the estimation of albumen by the side of the burette with its standard solution; and I hope on some future occasion to be able to state definitely how near I can approach quickly at the bedside the results which can only proceed from the laboratory with its attendant delay. I must content myself in the present communication with my notes on—

THE QUALITATIVE ESTIMATION OF ALBUMEN.

When picric acid was brought forward by Dr. G. Johnson as a remarkably delicate test for albumen, it occurred to me as likely to assist in deciding the sensitiveness of the various albumen tests from clinical evidence rather than from the laboratory, to take a series of urines containing very small proportions of albumen, to subject them to all the best-known tests, and to carefully tabulate the results. Since then I have met with twenty urines, among others, which supplied the required condition, all being faintly impregnated with albumen presumably derived from the presence of a small quantity of pus, or of blood, or of both, as determined by the microscope.² The table of results annotated at the time of every testing is before me. All the urines were acid except one, which was alkaline. The reagents employed were the following:—

1. Strong nitric acid.
2. Boiling the sufficiently acid urine and afterwards adding dilute nitric acid.
3. Saturated solution of potassium ferrocyanide, and the urine freely acidulated by citric acid, as suggested by Dr. Pavy.
4. Saturated solution of picric acid as advised by Dr. George Johnson.
5. Acidulated brine after Dr. Wm. Roberts.
6. Standard solution of potassio-mercuric iodide, after Tauret, and recently brought to notice by Mr. Stephen, with this modification—strongly acidifying the urine with citric acid instead of acetic.

The test fluid and the urine were in all the experiments brought into contact, as in Heller's method of using strong nitric acid, and the line of juncture was carefully examined for at least five min-

¹ Hence the fact of many medical men having given up urine testing entirely during their rounds.

² Whenever albumen was detected by any of the reagents mentioned in this paper, the urinary deposit was subjected to microscopical examination, and the impregnation was indicated, or at least suggested, by the presence of blood, pus, or casts.

utes. Out of the twenty urines strong nitric acid failed to indicate the presence of albumen in sixteen instances, boiling in fourteen, acidulated brine in fourteen, and potassium ferrocyanide in twelve; while picric acid and potassio-mercuric iodide gave a distinct and generally a sharply-defined ring of precipitated albumen in every case. The reaction was indicated by varying degrees of rapidity by the different tests; I must name the potassio-mercuric iodide and picric acid as the readiest; and of the two I would, if pressed for a preference, decide in favor of the former. I found as a rule strong nitric acid, acidulated brine, and potassium ferrocyanide much slower whilst bringing to light mere traces of albumen. I should here remark that I do not attach much clinical importance, so far as I can see at present,³ to the ability which the most sensitive of these tests possess in the detection of albumen in minimal proportions; for if I did not do so it might be justly thought by the practical physician that such observations as these indicate an ultra-refinement in testing of no utility in daily-work. They were simply made for the definite purpose of affording data suggestive of the most thorough of all the best tests for the discovery of albumen in urine; and as such they undoubtedly point to the potassio-mercuric iodide and picric acid; and to potassium ferrocyanide and acidulated brine as next in order. I should remark that, with regard to potassium ferrocyanide, I am not quite satisfied that the method (Heller's) followed throughout these observations for the sake of uniformity in obtaining the comparative results, fairly put to the trial the capacity of this test as an albumen precipitant, for on several occasions I noticed the production of a very slight opacity all through the urine instead of a well-defined ring. I am, therefore, with this qualification in my mind, inclined to think somewhat better of it than the above-recorded number of failures might lead anyone to suppose. The outcome of these observations, as well as of more recent ones, suggests to me the grouping of the tests in the following rising order of power to detect small quantities of albumen:—1. Strong nitric acid and boiling. 2. Potassium ferrocyanide and acidulated brine. 3. Picric acid, potassio-mercuric iodide, and the two new tests brought forward in this paper. I have, as a rule, found the members of each group to be nearly equivalent, and confirmatory of each other; and, further, the albumen which strong nitric acid and boiling discovered was always detected with greater facility by all the other reagents, and those tests which comprise the third group frequently revealed traces which the others failed to bring to light; lastly, potassium ferrocyanide and acidulated brine certainly took precedence over strong nitric acid and boiling. As confirmatory of the foregoing observations I may mention that I lately supplied an analytical chemist with some strongly albuminous urine, and he subjected it in the following way to a comparative examination by strong nitric acid and the tests I am introducing in the paper form. After diluting the urine until the albumen was just detectable by the acid, he proceeded to further dilution, when the reaction failed to appear, though still the more delicate paper tests distinctly indicated the presence of the albumen. The albumen precipitants which I find work well as test papers are: potassio-mercuric iodide, potassium ferrocyanide, the two new tests, and picric acid.

1. *Potassio-mercuric iodide* was introduced by Mr.

³ Since writing the above, observations have, however, caused me to modify my first-formed impressions as to the clinical value of the keenest albumen precipitants as at present known.

Guy Neville Stephen to the readers of this journal as an albumen precipitant discovered by Tauret, of Troyes. I select it for production as a test paper because I formed a favorable opinion of it while working it side by side with the other tests, and because it enables one to readily determine the quantities of albumen at the bedside. I moreover found that this double halloid mercuric salt could be evaporated to dryness on filtering paper without impairing its albumen-precipitating power; and the charge thus communicated still retains its integrity, though introduced over six weeks ago. Each paper contains one-fifth of a cubic centimetre of a standard solution, the formula for the preparation of which I hope to give in an article on the "Quantitative Estimation of Albumen at the Bedside," after my return from a holiday abroad. In the mean time I should say it differs considerably from that given in Mr. Stephen's paper. Hitherto, whenever the presence of albumen was indicated by this test paper, corroboration was furnished by picric acid, and the other tests of kindred power; and when the amount of albumen was such as to bring it within the range of less sensitive reagents, these also afforded confirmation. This mercuric salt is said to cause a quasi-albuminous precipitate in the urine of patients taking alkaloids; but I am not yet convinced of the correctness of this assertion, which I must leave, from want of conclusive evidence, neither positively confirmed nor denied. To this test I have repeatedly subjected the urine of one patient taking six grains of extract of opium every night and two grains of eodeia twice a day, of another having two daily subcutaneous injections of morphia and atropia, and of another taking fifteen grains of salicine three times a day with this result: a very faint cloud on adding the paper and a delicate ring by the "contact" method of testing; but the same reactions followed the use of picric acid, and the microscope revealed the presence of pus cells. After giving up the salicine, the urine still gave the same faint indications of albumen in small quantity. But should this source of error exist, it is not likely to induce more than a semblance to the merest traces of albumen, and it is, moreover, easy to guard against it. Then, again, should a patient be taking an alkaloid, this series of test papers provides other equally sensitive albumen precipitants.

2. *Potassium ferrocyanide*, when deposited to saturation on filtering paper, produces in conjunction with citric acid paper a reliable work-a-day test for the detection of albumen in urine. In my hands it has proved almost as sensitive as the other test papers here brought forward. The idea of combining the ferrocyanide with citric acid originated with Dr. Pavy, who proposes to introduce them to the profession as a compound pellet. As thus presented, this albumen test will doubtless be compact, portable, cleanly, and efficient. Perhaps, however, some practitioners may prefer to carry in their visiting lists, or otherwise, a leaflet of combined ferrocyanic and citric paper, rather than a bottle or other vehicle enclosing the pellets. The great convenience of this test paper, as of all the others, must appear when it is known that at the bedside no further apparatus is required for the detection of albumen than a teaspoon or a wine-glass.

3. *Two new albumen precipitants*.—During the past few weeks I have become acquainted with two precipitants of albumen in urine, which so far as I know, have not received attention from the profession—at any rate in this country; and I am not aware that either of them has been hitherto ap-

⁴ Op. cit.

plied as a urinary test. But until lately I felt some hesitation in introducing them to professional notice, lest by doing so I should unhappily create greater uncertainty as to the choice of the best and most generally useful albumen precipitant for clinical purposes than at present prevails; for I take it that medical men—at any rate many of the readers of *THE LANCET*—are just now somewhat perplexed by the rival claims of picric acid, ferrocyanide of potassium, acidulated brine, and potassio-mercuric iodide on the one hand, and by their adhesion to the older methods, in which they have trusted so long, on the other. But favorable observations as to the clinical efficiency of these, what may be styled the latest competitors, and a desire to extend my paper method of analysis to other reagents, which may at least be sometimes usefully employed to determine results of a doubtful character, have decided me to ask my brother practitioners to give these new tests a trial by the side of the others.

(a). *Potassio-mercuric iodo-cyanide*.—While working with mercuric cyanide for another purpose, I found that when alone in saturated solution in water it failed to cause a precipitate in albuminous urine, highly acidulated by citric acid; but when mixed with potassium iodide, it threw down the albumen at once as a voluminous white cloud. The iodide and the cyanide combine, and produce a new double mercuric salt ($4KI, HgCy_2$), which crystallizes out of solution as beautiful colorless needles. When the solution of this iodo-cyanide is acidified by citric or other acid, a gas (hydrocyanic acid) is liberated, which when completely expelled by heat, leaves the albumen-precipitating power of the solution unimpaired. It would therefore appear that this free hydrocyanic acid takes no part in throwing down the albumen, and that the precipitation must be ascribed to the mercuric iodide combination with potassium iodide. If so, this is but another form of the potassio-mercuric iodide test; but whether it will prove in some way more useful than the latter, I cannot as yet say. It can, however, be readily reduced to paper; and when thus employed, I have always found it as rapid and as sensitive as the other albumen test papers, all of which have hitherto afforded corroboration of its integrity and trustworthiness as an albumen precipitant.

(b). *Sodium tungstate* is another delicate test for albumen in urine. According to the *Journal of the Chemical Society* for March, 1874, it is stated that this salt had been employed by F. L. Sonnenschein as a sensitive blood test, producing with ammonia a deep green color, even when the blood was so dilute as not to be recognizable by the spectroscope, and as an albumen precipitant in the presence of acetic or phosphoric acid. I suppose this important observation has not attracted the notice of clinical observers, for I am not aware of any references to it in the medical journals in its obvious applications to urinary analysis. On mixing together equal parts of the saturated solutions of the tungstate (one in four) and of citric acid (ten in six) and of water, I obtained an albumen precipitant of great delicacy, rapid in operation, and one moreover, so far as I have ascertained, devoid of all objectionable qualities. When merely dropped into the urine, or used after the manner of Heller, it has always quickly revealed the same minimal proportions of albumen as could only be brought to light by picric acid and by the other tests of equal keenness. But this combination, when evaporated to dryness on filtering paper, did not give results so satisfactory—they required about a minute to develop—as when, after previous acidification of the urine by citric acid, a paper charged with sodium tungstate only was

used. The further capacity of this reagent as a detector of blood, at any rate in urine, I am sorry to say I cannot as yet confirm. Perhaps one or other of these albumen test papers will be found equally convenient in the consulting room as in the daily round; but should any practitioner prefer for the former a single solution, which will not stain the fingers, be free from all objectionable qualities, and will, moreover, be stable and always ready for use, let me specially mention the acidified solution of tungstate, which has given me every satisfaction, and which I now prefer to any other liquid test for home use. Sodium tungstate is procurable as dry, non-deliquescent crystals, and is, moreover, very cheap; for a shilling will purchase as much as can be needful for the detection of albumen during the whole life-time of the busiest practitioner.

Citric acid.—All the foregoing reagents are inoperative as albumen precipitants unless the urine is highly acidified; their application should therefore be preceded or accompanied by a sufficient charge of acid. For this purpose citric acid is easily made available when deposited to saturation on filtering paper, and in this form it has afforded me uniformly satisfactory results with all the albumen test papers.

Compound papers.—Instead of using citric paper separately prior to the reagent paper, it has been combined by a thin layer of rubber with the latter as a single test paper in the case of sodium tungstate and of potassio-mercuric iodide.

4. *Picric acid* can be deposited to saturation on filtering paper, which becomes a most compact and cleanly vehicle, and which, moreover, quickly delivers its charge to water. Repeated observation has shown me that when united with citric acid, as in the test papers, picric acid is divested of all the objections that have been urged against it. A few drops of albuminous urine instantly turns the bright picric solution, extemporaneously prepared from the test paper, into a muddy one, while the addition of more urine does not redissolve the precipitate as when picric acid alone is used. For the detection of small quantities of albumen (less than 1 per cent.) the "contact" method of testing is necessary; then it is best to make the picric solution in a wineglass, to take it up by the medicine dropper, and to glide it gently over the urine in the test tube.

How to use the test papers.—About thirty minims of the urine are taken up by a nipple pipette, or medicine dropper, and transferred to a short test tube, preferably one about two inches in length. If turbid from urates, it should be gently heated. It is now strongly acidified by dropping into it a citric paper, which is shaken about for a few seconds, and may then be withdrawn or allowed to remain. It is not now necessary to ascertain if the urine is sufficiently acid, therefore without delay the test paper selected is allowed to fall into it. A simpler plan, and one which I find answers equally well, is to drop both the citric and the reagent papers into the urine, so that they may fall together to the bottom, and to one side of the test tube. The latter is now inclined, so that the urine may repeatedly and slowly flow over the paper; when, if albumen be present in small or medium quantity, a whitish cloud will very quickly gather above and below it, the more readily detected by intercepting the light by the hand, etc.; while, in striking contrast, the upper part of the urine will remain clear. If, however, the albumen exists in large proportion, it will not usually produce a haze about the paper, but will coagulate on it, and will slowly fall from it in clots. Then, in any case, on shaking the tube the urine will become less or more opaque, according to the amount of albumen

present. If, on the other hand, the urine preserves its brightness, or if any turbidity it possessed prior to the introduction of the test paper is not increased, it may be inferred it is free from albumen. But inasmuch as it is just possible, though I have never found it so, it may not have been sufficiently acidified to enable the reagent to throw down the albumen, it is advisable to dispose of this suspicion by adding another citric paper; when, if no precipitation occurs, albumen is absent. The whole proceeding, of course, takes up very much less time than that occupied in reading this description of it. The reaction is practically instantaneous when the urine has been freely acidified prior to the introduction of the test paper. It is, however, not so quickly obtained, though the delay only amounts to a few seconds, when, without previous acidification, the single compound test papers are used. The convenience and simplicity of the testing for albumen by these combined papers are very great, for the practitioner only requires to carry them in his visiting list or pocket book and to drop one into a little urine in a teaspoon or wineglass, when, after stirring it about for a second or two, the opacity of precipitated albumen will appear. Those who prefer to develop a zone of precipitation along the plane of contact of a test solution and the urine, can do so by aid of these papers. A test tube and a wineglass are required. Into the latter the reagent paper rolled up is placed with about fifteen minims of water, and, without shaking, is set aside, while a similar quantity of urine is put into the test tube with citric paper. After withdrawing the latter, the reagent, now in solution, is taken up by the pipette and is allowed to trickle down the side of the tube, in which it will collect at the bottom. After developing the ring, the two fluids may be shaken together, when the albumen will be more largely precipitated as a milky cloud.

The keeping power of the test papers.—None of the papers have been bottled or kept from the air and light during several weeks; on the other hand, they have been purposely exposed without covering. Still I cannot discover the least deterioration of their power to precipitate albumen or any change of color or of other physical quality. From the first I rather suspected the mercuric papers might not stand the exposure of daily work for any length of time; but I am now of opinion I over-estimated, if I did not misjudge, this possible source of failure. I am surprised they do not partake more than they appear to do of the deliquescence of the potassium iodide, which is merged in the new definite salts with which they are charged; for it was only after free exposure in a dampish room without a fire, a trial to which no delicate test should reasonably be submitted, that they became slightly limp, but even then without showing any diminution of their albumen-precipitating property. So far I can assert I have seen nothing to cause me to doubt the stability of even these reagents employed as test-papers, and they are the only members of this series of albumen precipitants which *a priori* might be thought at all susceptible to the deleterious effects of atmospheric influences. Though referring to a test touching another subject, I may say that my cupric papers, designed for the qualitative and quantitative estimation of sugar, and made over two months ago, are to-day as good and as sensitive as they were when freshly prepared.

In a leader of the *Medical Times and Gazette* for 1874 will be found the following passage, which tersely expresses the opinion of the writer as to the trustworthiness and adaptability to the requirements of medical work of the tests for the detection of albumen as then known: "The reader

(21)

who has followed us so far will, we think, agree with us that none of the common tests are quite satisfactory, and that we still lack one which shall be cleanly, portable, cheap, and certain." I leave it for my readers to decide whether this remark still holds good.

In concluding these notes on the qualitative tests for albumen, I must state my consciousness of the imperfection of isolated observation, however faithfully recorded, and I would fain seek the scrutiny of many eyes, to correct if needful, or to more truthfully limit, any of the matters here advanced. With this object in view I have asked Mr. Hawksley, 357 Oxford-street, W., to place a limited supply of these test papers at the disposal of the profession, and to furnish gratuitously the series to anyone who desires to put them to a careful trial, and who will kindly communicate the results of their observations to me or to *THE LANCET*. In the meantime I hope that favorable evidence will not be long forthcoming to prove, as I have found, how satisfactorily they meet the requirements of daily work at the bedside, and to indicate which of them should be regarded as the best workable tests.

Harrogate.

ANTE-MORTEM COAGULA IN THE RIGHT CHAMBERS OF THE HEART AND PULMONARY ARTERY.

By JOSEPH EWART, M.D., F.R.C.P. Lond.

I NOTE from *THE LANCET* of March, that Sir Joseph Fayrer has recalled the attention of the profession to a mode of death which may occur after injury and operations in hot and malarious countries, occasioned by the formation of decolorized coagula in the right auricle or ventricle of the heart or both, and often extending, to a greater or lesser extent, along the distribution of the pulmonary artery. He, I think, appropriately associates this very mortal condition with some hitherto not fully understood lowered vitality of the blood and its containing apparatus, induced by the action of malaria upon the vaso-motor centres and the hæmopoietic organs. Under such circumstances, although no very marked or discernible deterioration of the general health may be apparent, and especially if the temperature be high and the atmosphere very humid, even slight injuries and moderately severe operations may and do, often unexpectedly, end unfavorably from this cause, but for the appearance of which the cases would, in all probability, have terminated in recovery. When there are manifest evidences of malarial poisoning, such as the facies miasmatica, anæmia, portal plethora, impeded and disturbed digestion, feebleness of the circulation with or without splenic or hepatic enlargement, etc., the danger of death proceeding immediately from the precipitation of these ante-mortem coagula is proportionately increased; and when, as is frequently the case, during the malarious season in India and other tropical or tropoidal regions, the patient is actually suffering from recurrences of periodic fever, or may have recently been so affected, the risk of a fatal issue from this among other causes is so over-ruling that, except on a careful calculation of the chances to save or prolong life, surgical interference had better be postponed, because experience shows that it is unjustifiable.

The group of cases referred to as occurring most frequently in hot and malarious countries is distinctly demarked, according to my experience, from the still larger class in which ante-mortem coagula in the right cavities of the heart and pul-

monary artery often expedite, or constitute the immediate cause of death, in cases of surgical or puerperal septicæmia and pyæmia and other exhausting diseases. Not only is this deposition of the fibrin of the blood in the right cardiac chambers often the immediate cause of death after surgical operations and injury in tropical and malarious climates, and altogether independent of any recognizable septicæmia or pyæmia either during life or on post-mortem examination, but I have repeatedly observed that in purely medical cases of malarial poisoning, where the patients, though not in what would be called robust health, have been able to go about their ordinary avocations, death has supervened from the obstruction caused by the more or less rapid accumulation of decolorized coagulum in the right auricle and ventricle, or in the pulmonary artery after what, at the commencement, seemed to be a trivial complaint. That such coagula may and do occur under similar bodily conditions, more frequently after operations and injuries, need therefore create no surprise.

What may be the exact nature of the changes in the blood and its conducting channels which favor and promote the precipitation of its fibrin with such fatal effect in the situation and manner described, it is, in the existing state of our knowledge, impossible to say. The fact, however, remains that in persons who have been subjected to malarious influence, and more particularly in those who have suffered from any of the types of periodic fever and sustained some damage, though not always apparent, to the vaso-motor centres, spleen, liver, and blood, the possibility of death supervening from an ante-mortem clot, so filling up the right cavities of the heart and the pulmonary artery as to fatally obstruct, in a preponderating majority of instances, the cause of the circulation through the lungs in surgical cases in India, is a contingency which, since Sir Joseph Fayrer first directed attention to the subject in 1866, can scarcely any longer be excluded from consideration either before or after operation.

Brighton.

OBSERVATIONS, CLINICAL AND SANTARY, CONCERNING THE BACILLUS OF TUBERCLE.¹

By G. A. HERON, M.D.,

Senior Assistant-Physician to the City of London Hospital for Diseases of the Chest.

IN June last I began to give attention to the clinical aspect of Koch's great discovery of the bacillus of tubercle. Sixty-two patients, amongst others, have since that time come under my observation in whose sputa I have detected this organism. I selected these cases almost exclusively from hospital practice, and I submitted them to special examination, because they seemed to me to be types of that kind of disease in which the bacillus should be present in the sputum. Were I asked to describe these patients, I should say that they were people of both sexes, and of various ages. The youngest of them, a boy, was ten years of age, and the oldest was a man of sixty-five. The majority of them were between twenty and thirty years of age. These persons were not distinguished by the prevalence amongst them of any particular color of the hair or eyes, nor of any special temperament. They were examples of the ordinary English working-man and woman. Their moral conditions were probably as various as they

well could be. Many were evidently hard-working, sober people, leading a life of constant toil. Others could not, with any approach to truth, be described as either sober or hard-working. This last class, I am bound to say, was not largely represented. It is obvious that no sound conclusion can be come to from a consideration of any possible connection between the occupations in which these people were engaged and the disease from which they suffered. Their number is too limited for any such purpose, and besides that, there were amongst them tradesmen of various kinds in a small way of business, costermongers, a city missionary, watermen engaged on the Thames, sailors, tailors, tailoresses, shoemakers, a policeman, soldiers, railway servants, cabmen, domestic servants of all grades, from men and women who said they were cooks, down to the poor creature who was evidently the drudge of a low-class lodging-house, but who called herself a "general servant." The physical examination of these patients showed them to be, with very few exceptions, more or less emaciated. Even those who formed these exceptions, told of how they had observed that they had lost flesh, and that they felt unfit for work which had formerly been no great trouble to them. All of the sixty-two showed evidence of disease of the lungs; flattening and impaired movement, more or less marked, of the chest walls; dulness at the apex or apices, or elsewhere over the lungs, and compromising these organs to a greater or less extent; râles, varying in kind from the mere click to the metallic ring, as of bubbles bursting in an air-filled cavity. In short, these patients showed, in different degrees, the usual symptoms which we associate with phthisis. Bronchitic signs and the rub of an inflamed pleura, were common occurrences. I wish again to say, that all of these cases were selected because they seemed to me to be unmistakable examples of phthisis. In three of these patients I searched the sputa weekly for the bacillus, but failed to find it until the third week in two instances, and the seventh week in the other case. In one of the two patients in whom the bacilli were not detected until the third week, the organisms, few at first, increased in numbers with wonderful rapidity. My experience of these sixty-two cases inclines me strongly to the belief, that the presence of these organisms in the sputum of any individual is, of itself, sufficient to stamp that person as suffering from a type of disease whose identity is fixed by the presence of the bacillus of tubercle, no matter what other peculiarities may seem to mark the disease.

I venture to think that the prognosis of cases of consumption will, for the future, hinge upon the observation of certain points in connection with the presence and appearance of the bacillus. I believe that amongst the most important of these are the numbers and the forms in which the organism is found in the sputum. I think that it will soon be established to the satisfaction of all who give attention to the subject that, given a persistence for some weeks of fewness of the bacilli of tubercle in the sputum, and that case will probably run a long course. On the other hand, I think that, given persistence of a large number of bacilli of tubercle, in the sputum early in the history of a case, and that case will run a short course, and end in death. Of these cases the most rapidly fatal, in my experience, have been those in which the bacilli were seen grouped in numerous masses throughout the sputum; grouping in masses may be seen in cases in which the bacilli are not very numerous, as well as in cases in which they are present in large numbers. The feature to which I now refer is, that the masses of

¹ A paper read before the Society of Medical Officers of Health, on Dec. 15th, 1882.

bacilli are so numerous as to give a characteristic appearance to many of the microscopic fields. I should describe three or four bacilli in a field as indicating the presence of few of these organisms; when their numbers rise to, and persist at, about thirty or more in a field I should say that the bacilli were numerous.

And now as to a part of this subject to which the medical officer of health cannot but attach great importance. Dr. Koch, as he says himself, undertook the work which resulted in his great discovery of the bacillus of tubercle in the interests of the public health. He fills the post of Officer of Public Health in Berlin. In the record of his researches upon tubercle, he shows how deadly were the effects of sputum containing the bacillus of tubercle when animals were inoculated with it. He allowed the sputum to dry, as it may sometimes be seen drying upon a hospital floor, not always in an out-of-the-way corner. Dr. Koch found tuberculous sputum, dried in this way, to be as surely fatal in its results when an animal was inoculated with it, as had been the case when he inoculated with the bacillus which he had obtained by cultivation of the organism from tuberculous tissue; and those who are familiar with his work will know the full significance of that statement. Now, if Koch's experiments with tubercular sputum are correct, there open out to us probabilities, which have facts for their foundation, concerning the way in which phthisis is spread amongst men. Taking his views as true, we must admit, it seems to me, that the expectoration of a consumptive person probably always contains, in a greater or less amount, a poison of the most virulent kind. Apply this to occurrences which must have been frequent in the experience of every medical man. I cannot better illustrate what I mean than by relating to you an experience of my own. Not long ago I saw a patient, for the first time, who was far advanced in consumption. While I was examining her chest she was seized with a violent fit of coughing. When it had passed off, she asked the nurse to give her a handkerchief. After spitting into a vessel what had been coughed up, she wiped her lips with the handkerchief, and the nurse laid it upon the mantel-shelf. In the course of my visit there was a second but slighter attack of coughing, and after it the patient took another handkerchief from below her pillow and passed it over her lips. Now, here were sources from which, with Koch's work before us, we cannot say that it was impossible for infection to spread. I think that if we believe that Koch has shown us the truth about tubercular sputum, we are bound to regard it as, at least, very possible that, without proper precautions, these two handkerchiefs might have conveyed tubercular disease to other people, for I found, on examination, that this patient's sputum contained bacilli in large numbers. These handkerchiefs might have been thrown into a soiled linen basket containing other articles, and sooner or later they must all have been washed. Again, consumptives often live for years after their disease has declared itself, and how many of these sufferers habitually keep a handkerchief under their pillows? If these things are so, how comes it to pass that tubercular disease does not go very near to exterminating the human race? That is just one of the questions to which we must now search for an answer. That tubercular disease does not readily pass from man to man in the ways now hinted at, is a view which accords with all our present knowledge of the subject. But there is a long distance between the belief that tubercular disease may be propagated by those means, and the belief that such modes of propagation are common. What the truth about this question exactly is we do not yet know. But

there are other possible sources of infection, for Koch has demonstrated the presence of the bacillus of tubercle in horses, cattle, sheep, dogs, cats, rats, mice, hens, and other animals with which men come into frequent contact. It is true that we do not know that tubercular disease has ever passed from the lower animals to man; but it is also true that we do not know that it has not so passed. In estimating the worth of Koch's work, we must not forget the fact, that the presence of the tubercle bacillus in certain cases of disease has already been verified by a large number of observers in Europe and in America, and we must, of course, give such a significant fact as this its full weight.

The question, How does phthisis spread amongst mankind? is probably one of the most difficult which medicine has to ask. I venture to think, that in the future we must search for the answer to that question in the light which Koch has shed upon it by his brilliant work.

Deductions.—1. The presence of the bacillus of tubercle in sputum is of itself sufficient to fix the identity of certain cases of disease. 2. The course which such cases will run is indicated by the number and grouping of the bacilli in the sputum. 3. If we accept as true Koch's recent work on tubercle, we are bound to take precautions against the possible infection of healthy persons by means of sputum containing the bacillus of tubercle.

A SUCCESSFUL CASE OF GASTROSTOMY.¹

By F. KING GREEN, F.R.C.S. Eng.

Surgeon to the Bath Mineral Water Hospital, and Senior Assistant-Surgeon to the Royal United Hospital.

THE operation for gastrostomy for cancer of the œsophagus is receiving a new interest from the profession. Simple, bloodless, and easy of performance, yet there was none more fatal, until Howse, recognizing the fact that the peritoneum, if placed under favorable circumstances, possesses healing properties second to no other tissue in the body, devised the plan of dividing the operation into two portions, separated by an interval of a few days. The success which has attended this method has rendered his name inseparable from the operation, and I have much pleasure in adding another successful case to those already published.

The patient, a lady aged fifty-six, was sent to me in August last by Dr. Fox of this city. For many years she has suffered periodically from slight dysphagia; these attacks were sometimes months apart. Twelve months before consulting me she first noticed a persistent difficulty in swallowing solids, which slowly increased until, when I saw her, she could only swallow thin liquids, and these with prolonged and painful efforts. Occasionally food regurgitated. A soft œsophageal tube passed for diagnostic purposes met with firm obstruction opposite the cricoid, beyond which no forcible attempt was made to pass it. The tube, on withdrawal, was covered with bright-red blood. Externally there was slight fulness in the lower part of the neck, with induration of thyroid and loss of the natural lateral mobility of the trachea, which, with the thyroid, seemed fixed posteriorly. Tenderness on pressure was revealed, and two or three enlarged and hardened glands existed in this region. A slight inspiratory stridor was perceptible on exertion, and occasionally a remarkable intermission of every fourth beat of the pulse, last-

¹ Read before the Bath and Bristol Branch of the British Medical Association, Dec. 9th, 1882.

ing for an hour at a time. Emaciation was well advanced, and debility kept pace with the emaciation. Eucemata of beef and porcine pancreas juice were ordered. A preliminary examination of the abdomen revealed the liver drawn down on the right side to a level with the umbilicus, and quite fixed; in fact, the right hypochondrium was entirely occupied by a solid substance as far as the median line, between which and the left cartilages, however, the abdomen was soft and resonant. The stomach note was normally placed. I operated on September 11th. I found, as anticipated, that the liver was absent to the left of the median line, and the stomach was in immediate relation with the diaphragm, through which I felt with my finger the immense power of the heart. The stomach presented at the wound, the part presenting being the centre of the anterior wall. This I secured by eight catgut sutures, which were made to include half an inch of the apposed peritoneal surfaces. The operation was antiseptic, and methylene was administered. The line of incision was a finger's breadth from the cartilages, and during the operation I found that the peritoneum and fascia transversalis contracted away from the outer margin of the wound, and became well drawn behind the costal margin; this was not the case on the other side. The effect was to give the wound a puckered appearance when completed. In fact the contraction was so powerful that the outer lip of the wound, in spite of the support received from the contiguous costal margin, became inverted, and on a posterior plane to the inner lip. I think if I had to do this operation again I should make the incision nearer the median line. For five days the progress was most satisfactory. Retching occurred once only. The pulse never exceeded 86; the temperature only once reached 99°. On the sixth day I opened the stomach and inserted a small rubber tube. The next day two pints of fluid food were given in divided portions, after which there was no stint of it. No leakage has ever taken place by the side of the tube (which is secured with plaster), for the simple reason that the tendency of the sinus is to contract against the eccentric pressure of the rubber tube, and so no moisture escapes. Twelve days after the operation the patient went out in her carriage. But, with convalescence from the operation, another set of symptoms began to develop. The inspiratory stridor, which was slight and occasional before the operation, became at last persistent and severe; the voice lost, and violent paroxysms of cough, accompanied with a dread of suffocation, left no doubt that the original disease was pressing on the recurrent laryngeal nerves. These symptoms advanced with such rapidity, that on the twenty-third day from the first operation I performed tracheotomy. She again made a rapid recovery, and in three weeks was again out of doors. At present, fifteen weeks from the first operation, her condition may be described as one of comparative comfort. She takes a drive when the weather permits, and her laryngeal symptoms have vanished. On referring to the medical literature of gastrostomy and gastrotomy I find sixty cases recorded, nearly all of them in *THE LANCET*, although I believe this does not represent the full number. Of gastrostomy there are eleven cases for the removal of a foreign body from the stomach; of these ten recovered rapidly and one died. The remarkable success which has attended this operation presents a striking contrast to the fatality of gastrotomy when performed for malignant disease; nor have we to look far for the cause of this difference. The eleven operations I have cited were performed on patients who were in possession of good bodily health and vigor. They had not been

subjected to a chronic process of starvation, combined with the debilitating influence of a cancerous cachexia; and in strong corroboration of this one has but to glance at the record of seven cases of gastrotomy performed for traumatic stricture of the gullet, produced, in each case, by the swallowing of a corrosive agent. All of these seven patients were under twenty-two years of age, and although in every case more or less exhaustion from chronic starvation was present, yet there was not superadded to this cancerous cachexia, and, moreover, they had youth on their side. Of these seven cases two died; one on the twelfth, the other on the twenty-eighth day; the report says from inanition, and probably this is correct. The operation in all probability had not been performed sufficiently early. One was by Howse's method; the other by the old (single) operation. Of the five which recovered three were by the old and two by Howse's method; so, if we may judge from so small a number of cases, it would seem that for traumatic stricture the single operation has been as successful as the double. But it is on turning to gastrotomy for malignant disease that we find Howse's operation more successful than the old one. I find that of twenty-two cases of the old operation twenty died within a week, and most of them about the third day; three died within a fortnight, and one lived forty days. Of twenty cases operated on by Howse's method, one is vaguely stated to have died ultimately, nine died within fourteen days, three lived until two months afterwards, one lived five months, one was stated to be going on well on the ninth day, one was discharged from the hospital relieved on the twelfth day, one was going on well on the thirtieth day. Three were living between four and five months after the operation, and to these may be added my own patient. I may state that in reading the reports of these cases, I frequently met with an expression of regret that the operation had not been performed earlier, and so a better chance given to the patient.

CASES OF PUERPERAL SEPTICÆMIA.

By FRED. C. CORY, M.D. St. And., etc.

THE following cases with the remarks appended may interest the readers of *THE LANCET*.

Mrs. R—, aged twenty-three years, a healthy and fairly strong young woman, was confined after a few hours of active labour of a well-nourished male infant. She progressed favorably until the third day, when I found her feverish, pulse 120, temperature 103.5°; furred tongue, great pain in the head, intolerance of light, pain in and distension of abdomen, lochia scanty and fetid, bowels and bladder acting, with very little milk in her breasts. At this stage I observed the infant to have purulent ophthalmia of both eyes. The house was not well drained; the bath room adjoined the lying-in one; the waste pipe of the bath I found to be untrapped and in direct communication with a sewer from which an immense amount of sewer gas was escaping. This was forthwith plugged, and I gave directions to have it trapped effectually. Fortunately I had with me a Higginson and a full-sized gum-elastic male catheter. Removing the patient to the edge of the bed with the nates well over the side, a waterproof sheet under her to protect the bed, and a good sized foot bath at hand, and a large jug of warm water, temperature about 96°, with the addition of a small quantity of salt, I connected the catheter by a piece of elastic tubing with the bone pipe of the Higginson, then introducing the former quite up

to the fundus of the uterus washed out the cavity of that viscus completely, to the great relief of my patient, she exclaiming, "My head is getting better." The stench was most offensive and abominable. This process was repeated daily for a few days combined with occasional warm turpentine flannels to relieve the abdominal distension. Bark with effervescing citrate of ammonia and a light nourishing diet soon put my patient on the convalescent list. The escape of sewer gas from the bath room was no doubt the cause of the uterine trouble, and probably added its quota as a factor to produce the purulent ophthalmia in the infant. No ergot was given in the labour. I mention this on account of a case I once saw where ergotine was subcutaneously injected in the arm for post-partum hæmorrhage. Erysipelas supervened, first around the needle puncture and then all over the limb, the patient suffering much from septic poisoning, and being in great peril for some time, although ultimately making a good recovery.

Mrs. D—, married at sixteen, had always enjoyed good health and never required the doctor except for her confinements, of which she had had already four healthy children, but always with "after trouble," as she expressed it. The coming accouchement she greatly dreaded. I carefully inspected all the drains and traps in the house, and found them working well. In due course she had an ordinary labour, occupying only a few hours. A strong healthy boy was born. On the evening of the second day she was seized with shivering, headache, abdominal pain and tenderness, lochia scanty and offensive, bowels obstinate, urine full of deposits, skin moist, pulse 125, temperature 103·2°, much restlessness, was very depressed in spirits and hysterical, no milk in the breasts. Great and immediate relief was derived from the washing out of the uterus and vagina, so much so that she had some hours of refreshing sleep, and relieving all the other distressing symptoms. The other treatment was by tonics, light and nourishing diet, which soon completed a cure. I could discover no cause for her "after trouble," as she expressed it. Eighteen months having elapsed, I was again requested by Mrs. D— to attend her. I advised her to obtain every article required for her accouchement quite new, even to bed linen, waterproof sheets, etc., having long suspected the enemy might lie concealed in the articles of clothing made use of at her confinement. A short time afterwards she was delivered of a healthy girl, and made a rapid recovery, entirely free from any septic trouble whatever, the surroundings being the same as in all the other confinements.

In thinking over this case I can come to no other conclusion than that the linen and bedclothes contained the fomes of disease. The above two cases are only types of a great many others having similar characteristics which I have met with in a large obstetric practice of some years' duration. Since I have adopted the plan of syringing out the vagina, and in some cases the uterus too, with warm water (a little salt added) on the second or third day, I have had no difficulty in preventing disease and procuring a rapid and complete recovery, saving the woman much suffering and much dosing with physic.

I have known the following cause post-partum septicæmia:—1. Bad drainage and escape of sewer-gas in the house—such as deficient closets, sinks, and waste water-pipes in cisterns untrapped. 2. Open gully-holes near the house and bedroom. 3. Surface drainage from other houses passing in ditches or watercourses. 4. Closets placed over stagnant ponds near to the house, which are common enough all over the country, especially at

farm-houses. (The farm stock always drink this pond water, and seem to prefer it.) 5. Dirty pigstyes near the dwellings of the poor. 6. Scarlet fever and erysipelas infections can be traced to have caused post-partum septicæmia. I have several times had to attend women in their confinements who up to that time had been constantly watching and nursing their children down with scarlet fever. Yet nearly all these women recovered without the slightest sign of after septic trouble.

During the epidemics of scarlet fever this fact is well known to every practitioner of medicine. I once had a case of severe traumatic erysipelas of head and face, with great constitutional disturbance and delirium, in a patient who was confined at the height of the disease. I dreaded the post-partum consequences, for she was a very valuable life. However, she had a good delivery, and made a rapid recovery, without any symptoms of uterine trouble. I do not infer from the above fact that the obstetrician should be careless in exposing his patients to unnecessary infection. He cannot be too careful in cleanliness, and in changing his clothing as often as needs be.

Buckhurst-hill, Essex.

ON A CASE OF PUERPERAL SEPTICÆMIA.

By ARTHUR PRICE, M.R.C.S.E., Etc.

On Sept. 23rd last I was called to attend Mrs. D—, a primipara, aged thirty-eight years, a very tall, strong, healthy woman. I found that she had had some hæmorrhage for twenty-four hours, due to a partial placenta prævia, which was forthwith detached. The labour proceeded satisfactorily, and very soon a female child was born. The placenta followed without aid shortly afterwards; it was carefully examined, and found to be complete. Scarcely any post-partum hæmorrhage occurred. The whole time occupied by the labour from the first call was under two hours. The three following days the patient, though anæmic, did fairly well; but on the 27th (the fifth day) she complained of pain over the abdomen, especially referred to the right iliac region accompanied by slight nausea, for which a saline and opium mixture was prescribed.—28th: Pain was easier: patient anæmic; dusky in countenance; had been vomiting. Temperature 103°; pulse 112; respiration 28. The nurse who was engaged by the patient had been burning pastiles, which, however, did not hide the effluvium from faecal matter. Asked if the bowels had been relieved, I was informed that such had not been the case, but that the nurse burnt the pastiles to hide the smell from the water-closet. Upon inquiry, to my horror and surprise, I found that the following sanitary arrangements existed in apartments for which the patient paid £600 a year; and of which the nurse did not consider it necessary to inform me:—Separated from the general apartment by a thin match-boarding, but in the room, was a water-closet used by her attendants as well as herself, the window of which, although communicating with the outer air, could not be opened; there was also in the room a sink into which an overflow pipe was constantly discharging water. To complete the disasters, the nurse had actually stored up in pails the whole of the linen that had been used by the patient since the day of the confinement, and from which, when the door was opened, a most disgusting odor arose. I ordered all the linen to be carbolized and removed immediately, drains flushed with carbolized water and not used, and the room sprinkled

with the same. The window of the water-closet to be taken out and the door kept closed. The patient refused to allow herself to be removed. Medicine ordered: effervescent mixture and opium, vaginal injections of carbolic lotion (1 to 100).—29th: Vomiting continued, pallor increased. Temperature 102° A.M., 104° P.M.; pulse 120; respiration 30. Continued the mixture. Pill of one grain of opium to be given every four hours, and half an ounce of brandy every four hours alternated with the pills.—30th: Sickness continued. Temperature 103·2° A.M., 104·8° P.M. No pain. Lochia and other secretions fair in quantity. Child still sucking and well. Ordered two grains of quinine with one grain of opium every four hours. Ten ounces of champagne in twenty-four hours at equal intervals. The nurse, who was most incompetent, was now dismissed and her place taken by two trained nurses.

Oct. 1st.—Sickness continued. Slight diarrhoea. Pain in right iliac region. Temperature 104° A.M. Dr. Potter, of Westminster Hospital, in consultation, ordered immediate removal from room, which was at once done. Continued pills. Medicine to be discontinued. Vaginal injections were used three times a day. Temperature 105° P.M., pulse 95.—2nd: Improvement after removal marked for a few hours, but towards evening temperature again arose. Lowest temperature 100·8°, highest 104·4°. Lochia profuse and offensive. Tenderness over abdomen. No tympanites. Milk, beef-tea, and chicken broth were given in small quantities every hour if awake, with half an ounce of brandy every four hours. Three motions very pale and clay colored.—3rd: Was very much easier. Slept well. Temperature, highest 103°, lowest 100·2°.—4th: Bowels relieved twice. Slight return of pain. Temperature fell slowly to 96·6°, but rose again after brandy. In the evening a slight rigor occurred, but soon passed off. Temperature 101·2°.—5th: Bowels relieved three times, motions still clay colored. Copious perspiration, with faintness; slight cough. Temperature: highest 100·4°, lowest 98·2°, pulse 120, respiration 42. Brandy essence and jelly were given frequently in small quantities. No pain.—6th: Great deal of pain in side. Tympanites over umbilical and right iliac regions. Temperature A.M. 99·2°, which during the afternoon steadily rose to 103·2°. A slight rigor again occurred at midnight. Pulse 122, respiration 36.—7th: In great pain; very restless. Again met Dr. Potter in consultation. A rigor had occurred just previous to his arrival. Temperature 104°, which fell in two hours to 96°. Fomentations for pain, hot water bottles, etc., were ordered. Temperature again rose in two hours to 102·6°, and then fell to 98° at 7 P.M. Death occurred at 7.45 P.M. A post-mortem was refused.

Remarks.—In this case we have present all the elements necessary for the production of puerperal septicæmia. A woman coming rather late in life to the birth of her first child with a certain amount of mental anxiety is confined in a room which might be more correctly described as a large water-closet without ventilation. She is then badly nursed, and the effluvia of foul cloths soaked in lochia allowed to still further defile the atmosphere. The removal to a somewhat purer air caused the balance to turn in her favor for a moment, but the system was too charged with poison to render the case anything but hopeless. It is only another and very marked instance of the importance of the doctor inquiring for himself into the sanitary condition of the lying-in chamber, and his being aided at the time of his attendance by a skillfully trained nurse instead of an ignorant and incompetent one.

Parkhurst, Isle of Wight.

A RARE CASE IN MEDICAL PRACTICE.

By H. E. SARGENT, M.D. Edin., etc.

Mrs. B—, aged forty-five, weighing 17 st., on May 7th, 1882, fell on a zinc pail, its edge striking the abdomen two inches to the right of, and on a level with, the umbilicus. A day or two after the fall a tumour, semi-elastic, with distinct outline, could be traced at the seat of injury. It was only slightly tender, and appeared to have deep-seated attachment. About July 20th the skin over the tumour began to discolor. Poultices were applied, and at the end of another week it commenced to slough. Gradually a black mass was disclosed, revealing the true nature of the tumour, which was evidently a blood-clot. This gradually became enucleated, and in due time was turned out, leaving a chasm in the abdominal wall, four inches wide by three deep. Cotton-wool steeped in carbolic oil was used to plug the cavity from the bottom, which rapidly closed. On July 10th Dr. Fenwick, of Harley-street, saw the case with me in consultation. After an exhaustive examination he accurately diagnosed the nature of the tumour as verified by its subsequent history. The case is interesting from its rarity, and the complete recovery under a strictly expectant plan of treatment, aiding the *vis medicatrix nature*. The fall must have caused muscular rupture at the seat of injury, with subsequent hæmorrhage into the cavity thus formed.

Shadwell, E.

CASE OF HYSTERIA; RAPID BREATHING SIMULATING CARDIAC OR DIABETIC DYSPNŒA.

By EDWARD MACKEY, M.D., etc.

DYSPNŒA, or rapid panting respiration, is recognized as a possibly hysterical symptom, but in certain good text-books not much stress is laid upon it. Thus Dr. Russell Reynolds says only "palpitation of heart, syncopal feelings, and dyspnœa are common enough, the latter, however, without notable change in the ratio of respiration to pulse"; and Niemeyer: "The patients complain sometimes of very great oppression, and breathe quickly and deeply; but by excluding all disease of the respiratory passages, of the circulation of the blood, and of nutrition, which might otherwise explain the increased 'besoin de respirer' one recognizes that there is only a hyperæsthesia, or at least an altered sensation." The following case illustrates, however, a decided alteration "in the ratio of respiration to pulse," and at the same time a source of difficulty when cardiac or hæmic disease is present; more applicable to it is a sentence of Dr. Bristowe's: "In some cases there is actual dyspnœa, which becomes so extreme as to demand operative procedure.....without apparent cause, and with a pulse but little elevated above the normal, the respirations will suddenly rise from 40 to 50, or even 70 to 80 in the minute, and continue thus for some minutes, or on and off for some hours, and yet without other evidence of dyspnœa or distress."³ I had never quite appreciated this description until I met with the following case.

On Nov. 10th, 1881, at 10 P.M. I was sent for hurriedly to find a girl, aged seventeen, sitting up in bed, breathing 88 to 98 times per minute, with

¹ System of Medicine, vol. ii.

² Handbuch, 2ter Band.

³ Theory and Practice of Medicine, p. 1082.

occasional convulsive gasps, and complaining of severe pain and oppression in the cardiac region. The face was blanched; the pulse feeble, 64; temperature 99° F. To her family she seemed dying. Six months before this date I had attended her for aggravated chlorotic anemia, all the symptoms of which had improved under iron, etc., except a loud systolic basic bruit, which had persisted unchanged, and was now so loud as to obscure all other chest sounds (it was this and the cardiac pain that gave apparently a serious complexion to the case). She had seemed a sensible girl, always occupied in house-work, etc., but recently had had disappointments, and for some days before the attack extra exertion both as to work and pleasure. The rapid breathing had commenced an hour or two before my visit. Reserving judgment as to the real nature of the attack, hypodermic morphia with atropia (in ordinary dose) seemed indicated, and certainly quieted all the symptoms; the girl slept, with relapses at intervals, and a purgative was required and given later, and then a few doses of bromide with digitalis. Next day she remained in bed, apparently improving, but on the following morning (Nov. 12th) relapsed violently; the respiration went up from 88 to 128 per minute, and in the afternoon the symptoms were so alarming that a consultation seemed desirable. Dr. Withers Moore then saw her with Mr. Verrall (kindly taking charge in my temporary absence), and whilst recognizing possible hysteria, they desired an examination of the urine with reference to diabetic dyspnoea. The fact of retention for many hours was then verified, and catheterism was attempted but resisted; the secretion, however, was free from either albumen or sugar; sp. gr. 1027. At the consultation a-quarter of a grain of codeia was ordered every two hours as a suitable sedative in any case. During the evening and night, respiration varied from 100 to 120 per minute; the pulse from 59 to 72. Nourishment was taken through a glass tube, but with much difficulty, as it made the breathing more rapid and spasmodic. Two drachms of brandy every two hours.—13th, morning: Pulse 68; respiration 68; temperature 98°. Had severe headache (brandy and codeia?): better now after tea. Has pain in the left shoulder, running down the arm, and numbness in the fingers of the left hand. 3 p.m.: Crying; agitated by visitors, etc. At 4 I received a hurried message that I "should not be in time for her last breath." Found her gasping with most urgent orthopnoea, apparently dying, the family in tears round the bed, and a clergyman giving the last ministrations of religion. Apparently she took no notice, but a slight quiver could be detected in her eyelids, and the pulse was regular, though slow and feeble. All present, except the mother, were sent away, the window was opened, morphia injected with atropia, and a blister painted over the epigastrium. In a few minutes I sent out word, in her hearing, that she was better, and this led to an explosion. She screamed, burst into violent passion, struck me, her mother, the bed, the wall, shouting, "Go away; I don't want you." Afterwards she said she saw "an old man with a bag," and meant her blows for him. The sedatives might have developed this delusion, but the dose was an ordinary one. She was ordered valerian and bromide by mouth or rectum, and at 10 p.m. sat up for bed-making. Pulse 60; respiration 48. A calomel pill was given.—14th: Slept well; water passed. Pulse and respiration about 60. 4 p.m.: Sent for, to find her in a wild and markedly hysterical condition, screaming, fighting, tearing clothes, curtains, etc.; four men were holding her. She was moderately chloroformed, became quiet and sensible in five minutes, and submitted to a turpentine enema.—

15th: Slept well from midnight. Pulse 60; respiration 80, occasionally normal. Is fairly quiet, but shows temper on the slightest provocation. At 10 p.m. she had a return of delusion and anger, which chloroform quickly subdued.—17th: Chloral with bromide was of service during the night, and valerian in the day.—25th: Has mostly lain in bed since; exhausted; but now is better, and getting up daily.—30th: A relapse.

Dec. 10th: Menses appeared, after a delay of one to two months.—18th: Relapse as to rapid breathing and excitement.

Jan. 7th, 1882: Going on well—i.e., sits up most of the day and goes out in a Bath chair, but seems "silly at times," emotional, over-affectionate, crying easily, "You don't care for me"; says she cannot walk, no confidence in moving, staggers across the room; apparently want of control over her limbs. Her chief attention is now given to her appearance, hair-dressing, etc., or trivial things, as dolls. This condition improved under sharp speaking, and directions in her presence that she should be left alone and not nursed too much. Zinc valerianate and wine of beef and iron.

Feb. 3rd: Found that she had hidden chloral, and to-day took an overdose that produced profound sleep; this was made a lesson to her, and from this date she gradually improved and resumed house occupations.

June 6th: Continues fairly well, but very pale and not strong; is growing; menses have intermitted once, but recurred recently; has no special pain over the heart, nor palpitation, nor dyspnoea, except on exertion, mostly when going upstairs or uphill. Pulse 80, regular, small, jerky, not visible; no epistaxis; no oedema. There is still a bruit, basic systolic, of maximum intensity about the third left costal cartilage, heard, though less, at the right; not propagated upwards; inaudible at apex or along the spine; it is rougher, less blowing than an ordinary hæmic bruit, though it is probably of the same nature; it is made louder by exertion; the second sound is accentuated at the base.

This case suggested inquiry into the distinctive characters of diabetic dyspnoea, and they would seem clearly different and distinguishable from such conditions as I have described. The severe diabetic form is rare, and in the course of many years' hospital and other experience I have never seen it. Kussmaul, in 1874, first drew attention to it as dependent on blood alteration, notably the presence of acetone. Dr. Cyr, writing in 1877, says, "the dyspnoea generally comes on suddenly and with violence; the inspirations are deep; both inspiration and expiration are prolonged; the air passes well into the lungs, but apparently does not oxygenate the blood; the attacks may recur several times, but finally the patient becomes unconscious; the duration until death varies from ten hours to three days." Dr. B. W. Foster, whilst lecturing in the wards of the General Hospital, Birmingham, was called hurriedly to a diabetic boy who had been going on favorably as an out-patient for many months, and had only been admitted the day before; he found him in a state of urgent dyspnoea, with a respiration of 32 per minute, "with deep, ample, chest-filling inspirations, taking in large volumes of air but without any satisfying of his craving;" chest everywhere resonant; pulse small, weak, 136; the symptoms commenced with sickness and pain at the epigastrium. The boy died the next day. The same physician has recorded another case—adult, with respiration 50 to 60 in the minute, long, deep, and filling, but not satisfying the air hunger, and another, similarly described, 30 per minute. Pro-

fessor Sanders in the *Edinburgh Medical Journal*, July, 1879, tracing the attacks rather to fat embolia than to acetonaemia, thus describes the condition in a diabetic man, aged twenty-four:—"He had intense dyspnoea, but with inspiration and expiration of extraordinary fullness and depth, like a man who had won a mile race; the ribs, etc., moved upwards and outwards to the fullest extent, and descended with exaggerated force; there were no râles; air entered freely, but he presented a picture of air-hunger, so insatiable that no violence of respiratory effort could appease it." Pulse, 100; temperature, 100°. The heart condition offered no explanation; stimulants gave no relief; after thirty-six hours he lapsed into coma and died.

In the same journal for September last is a case by Professor Fraser. A man of thirty-five, breathing 34 per minute and in an exactly similar manner. The face and hands were dusky, the pulse 154, weak. An additional diagnostic was afforded in this instance by drawing from the finger a drop of blood which proved of characteristic cream and pink color and full of oil globules.

These, and several other cases on record, all agree in the depth and fullness of the respiration, which in quickness seldom exceeded 40 per minute, and in character was altogether different from the shallow, very rapid breathing I have described. Violent epigastric pains may occur in both conditions. A rapid pulse is almost invariable in diabetic cases, and was present in all those quoted; Senator (in Ziemssen) and Lepin have drawn special attention to this. In my case the pulse did not exceed 72, and was commonly 60, a useful diagnostic point.

Brighton.

NOTES ON SURGERY

By WILLIAM S. SAVORY,

Surgeon to St. Bartholomew's Hospital.

On Syme's Amputation.

EVERYONE knows that Mr. Syme attached very great importance to certain details of the admirable operation of amputation at the ankle-joint that goes by his name. He insisted especially upon the position of the incision across the sole. "The foot being placed at a right angle to the leg, a line drawn from the centre of one malleolus to that of the other, directly across the sole of the foot, will show the proper extent of the posterior flap. The knife should be entered close up to the fibular malleolus, and carried to a point on the same level of the opposite side, which will be a little below the tibial malleolus." Thus he laid it down, and he dissected the flap off the os calcis from below upward. These directions were for a long while rigidly observed, but of late years surgeons have been less particular in the direction of the incisions. That across the sole is often made obliquely backward, at the expense of the flap. The incision across the front of the joint is also varied, sometimes being quite transverse, at others curved towards the toes. With regard to the heel, of course the more obliquely backward the incision of the sole is made the less difficulty will there be in the reflection of the flap, if done from below upward; but it seems to me of importance to preserve at least the whole of the heel, so that it is best to make the incision a vertical one. The thick integument of this region forms so capital a pad on the extremity of the stump that care should be taken to secure the whole of this, and to bring it well forward in the first instance, for during repair and afterward there is a tendency in this to be

drawn backward. Of course it will not be forgotten that after this operation the person stands and walks directly upon the extremity of the stump. With regard to the particular points where the extremities of the vertical incision should be, some surgeons keep them both on a level with the external malleolus, but I prefer to have them rather more forward—that is to say, on a line with the extremity of the internal malleolus, but not extending higher than the level of the external one, for the base of the flap is thereby so much broader. This is, I think, an advantage, and, so far as I can see, there is no objection to it. But of all changes in the operation I should attach most importance to the way in which the dissection is done. I greatly prefer, after making both incisions, to open the joint from the front, and then to work from above downward. This mode of dissecting out the os calcis is far easier than the original plan of dissecting from below upward, and there is less danger of inadvertently cutting into the substance of the flap. I have adopted this plan now for several years in many cases, and I cannot doubt that it is a much better one of performing the operation. By dissecting out the os calcis from above downward, and so escaping the only difficulty in the operation—that of turning off the heel—there is no temptation, as in the other way, by carrying the first incision obliquely backward, to sacrifice some portion of the flap.

On Ligature of Arteries.

Of late years a practice, which appears to me to be fraught with mischief, has come into fashion in the operation for ligature of important arteries in their continuity. I mean this: that after the neighborhood of the vessel has been reached by a few preliminary incisions, it has become the custom to lay aside the knife and to seek for and expose the artery by tearing through the investing tissues with the end of a director or some similar instrument. The motive for this practice, which, I think, has been derived from the Continent, is obvious enough, and similar to that which formerly suggested the use of a silver blade. It is the fear of injuring the artery itself, or of some branch near to its origin, by the knife, when dissecting closely upon it, and so of having to deal at a critical stage of the operation with troublesome hæmorrhage. But if the knife be used with fair knowledge and ordinary skill, the artery itself, or even a branch of it, ought not to be in danger; and assuredly the risk of yet more serious injury in another way from forcibly tearing through the textures with a blunt instrument is imminent. Indeed, it is almost impossible to avoid bruising the artery or vein, or to make a clean and satisfactory isolation of the artery by this plan. It gets exposed, indeed, and a ligature can be passed around it; but the surface of the vessel, when thus separated from its sheath, does not appear smooth as it ought to do, and already before the operation is finished there is often evidence of some extravasation of blood upon the surface. The less complete the isolation of the artery at the particular spot where the ligature is to be applied, so much the greater is the risk of injuring the vein by the needle. Herein, I think, lies the chief cause of the dangerous accident of transfixing the vein. If all the work of exposure and isolation of the artery is to be done with a director or some such instrument, if no cutting is to be allowed and only tearing practiced, what is to become of the rule, so universally insisted on, of opening the sheath with the least possible amount of disturbance, and of separating it from the artery only to an extent sufficient to allow the needle to pass? How is the sheath to be opened and treated, according to the

recognized principles of surgery, with a director? While it has happened to me, in more than a single instance, to see the artery injured both on the dead and living by the abuse of a director, I have never seen the artery itself cut by the knife, even when it has been used too freely by awkward hands. I believe a surgeon who is fairly up to his work will tie an artery more safely by exposing it with the knife than with such an instrument as a director, and there is probably no operation in surgery in which the result so depends on the manner of performing it. It is not enough to tie the vessel and nothing but the vessel. It is of supreme importance to tie the vessel with the least possible amount of disturbance or injury. And, while writing on this subject, I may add that, with this object in view, perhaps it is more convenient to carry the needle round the artery, without the ligature, and to pass the thread through it afterward.

FIBRINOUS COAGULA IN THE HEART AND PULMONARY ARTERY.

By SIR JOSEPH FAYRER, M.D., F.R.S.

(Continued from p. 320.)

In a recent communication I referred to thrombosis of the pulmonary artery and clots in the heart as a cause of death in certain diseases, and especially after injuries and surgical operations, even where there has been no indication of pyæmia or septicæmia. Though unable to explain the pathogenesis of this dyscrasia, I remarked that whilst it seemed to be most liable to occur in malarial climates where the subject of it had become more or less cachectic, yet it is not confined to malarially affected individuals, but may, and probably does, take place under other circumstances in all climates, and that it is perhaps a more frequent direct cause of death than is generally supposed. Of its importance as a cause of disease of a secondary character disseminated throughout the body in the form of local death, of parenchyma in the viscera, which, if life be prolonged sufficiently, become disseminated abscesses from suppuration taking place round the dead patches; or, again, of the influence of thrombosis of this character when it occurs in the arterial system, producing gangrene or other dangerous results, much might be said, and I have described it in detail elsewhere; but for the present I refer only to that form which affects the right side of the heart and pulmonary artery, whether in the form of clots moulded into the auricle and ventricle, extending into the ramifications of the pulmonary artery like the branches of a tree, or in the pulmonary artery itself; or it may be impacted in the form of a small nodule or flake in the ostium of the pulmonary artery, equally dangerous in its effects by preventing access of blood to the lungs.

The symptoms of this dangerous morbid state are described in the following brief abstract of cases, so it is needless to detail them further than to say that the impeded pulmonic circulation is indicated by hurried, gasping, painful respiration, and that the struggle for breath is often most distressing to see, as it is agonizing to the sufferer, who remains painfully conscious of his condition till the last. Happily in some cases, after a protracted struggle of apnoea, recovery occurs. I suppose by the disintegration and removal of the clot, which disappearing, is only too likely to cause secondary mischief as the result of the emboli thus carried into the pulmonic circulation. Where pulmonary or cardiac thrombosis takes place as

one of several conditions of exhaustive disease, or where it occurs in surgical fever, pyæmia, septicæmia, or in malarial conditions, whether of fever or of splenic cachexia, the symptoms are naturally all associated as part of the disease, and special prominence is not assigned to this as a cause of death. But when it comes on suddenly in a case which in all other respects appeared to be doing well, its pathological and clinical interest are enhanced.

An English sailor, aged twenty-nine, who had been living in Calcutta for some time, applied one morning at the hospital, and had a catheter passed for a slight stricture from which he had suffered for some years. The resident surgeon passed No. 8 with ease, and relieved him of retention of urine. He returned to the hospital at 3 p.m., saying he felt ill. He had a rigor after returning home in the morning, became restless, feverish, and delirious. On the 20th he had pain in the right hypochondriac region; his breathing was hurried, and his countenance anxious. He had had loose evacuations during the night. The breathing became more gasping, though air entered freely into the lungs. The distress rapidly increased, breathing became more hurried, and gasping, and he complained of a sense of choking. At 10.30 p.m. he passed urine freely. Stimulants of ammonia with quinine were given, and turpentine stupes applied; but no improvement took place, and the house-surgeon reported that he died in "a fit of gasping" at 11.30 p.m. There was no pyrexia, and he was perfectly rational to the last. His struggles for breath were most distressing to witness.

The post-mortem examination revealed lungs hypostatically congested. The liver was slightly enlarged but otherwise normal. The spleen was normal. The kidneys showed signs of commencing degeneration. The bladder was slightly thickened; the urethra slightly thickened. There was neither wound nor false passage. The tissues about the neck of the bladder were natural, so was the prostate. The pericardium contained a small quantity of straw-colored serum. The heart was normal, but its cavities contained firm adhering decolorized fibrinous clots. Those on the left side extended from the auricle into the ventricle, and thence into the aorta for about three inches. In the right cavities the clots extended on into the finer ramifications of the pulmonary artery; they were firm, decolorized, and adherent, and not only obstructed the ventricular and arterial openings, but extended far into the subdivisions of the pulmonary artery, ramifying like the branches of a tree. I made the following remarks on this case at the time:—

I have repeatedly noticed this condition as a cause of death in surgical cases, but I have never seen one more striking or more uncomplicated than this. I have before expressed my suspicions that malaria has much to do with inducing the condition of blood in which this fibrinous coagulation occurs, as a result of some disturbance of the innervation by a surgical operation. In this case the simple act of passing a catheter through a slightly strictured urethra was the exciting cause. The patient cannot be said to have been, strictly speaking, in a healthy condition, although he appeared in perfect health, and no lesion was discovered that could account for death. Sufficient, however, existed to suggest how, with the addition of the shock of the operation and the consequent urethral fever, the blood-change and consequent fatal apnoea were brought about. Something was said about his having recently suffered from intermittent fever, but no precise information on the subject was recorded. Be that as it may, he had none of the appearances of a person

suffering from malarious cachexia. But no one in Bengal can be said to be exempt, especially at that season of the year (June); and I am disposed to believe that this malarious influence is in persons of irritable constitution, and notably in those suffering from stricture, a predisposing cause of that dangerous condition in which fibrinous coagulation is likely to occur. It has long been known that death may occur rapidly from this cause in puerperal patients, and that in diphtheria, croup, cholera, and other exhaustive diseases it is not unfrequent; and in such cases, where the blood must be in an altered condition, and the muscular fibre of the heart weak, although the precise nature of the blood-change, may be obscure, it is not difficult to understand why a fatal result should occur. But in cases such as the preceding, and in many others where fatal apnoea has supervened suddenly from thrombosis of the pulmonary circulation after surgical operations, when the patient appeared to be doing well, it is more difficult to comprehend.

In the *Edinburgh Medical Journal* for April, 1870, p. 888, the following remarks were made by Mr. Annandale, now Professor of Clinical Surgery in the University, in reference to the death of a patient who had undergone amputation at the hip-joint:—"The disease in this case was a cancerous tumour affecting the lower third of the femur, and the patient lived until the fifth week, when he was suddenly seized with difficulty of breathing, and died in forty hours. The post-mortem examination showed a partially decolorized clot in the pulmonary artery. The surfaces of the flaps were firmly united; there was no abscess in the acetabulum; there were no traces of pyæmia." I then remarked, as I now repeat, that if the cause of death be sought for in all cases that terminate fatally after surgical operations, especially where there is cachexia, or where there has been much loss of blood, or where a large portion of the body has been removed, it will probably be found that this is occasionally the cause of death, and even after operations of much less severity than removal of a limb.

In August, 1871, I saw a young and robust Englishman, aged twenty-eight, of active, temperate habits, resident for some years in Calcutta, who was reported to be suffering from a swelling in the groin. He was feverish, with pulse 104, having had severe rigors previously. He had great thirst; bowels acted, voiding greenish matter. It was suspected that he might have hernia. The fever passed off early next morning. I found no signs of hernia. At 2 p.m. next day alarming symptoms came on; at 4 p.m. his breathing was very hurried, and his body was covered with cold sweat, with a rapid and feeble pulse. I found him sinking; dyspnoea intense; breathing gasping and hurried; face and lips dusky and livid; pulse imperceptible. He was quite conscious, and died within half an hour. The post-mortem examination showed that the inguinal canals were perfectly normal. The glands in the groin were somewhat enlarged. The intestines were normal, and no choleraic fluid was found in them. The lungs were hypostatically congested and oedematous, and the bronchial mucous membrane was also congested. The heart was normal and firmly contracted; it contained firm decolorized clots extending into both the aorta and pulmonary artery; all else was normal. This appeared to me an example of pernicious malarial action, and of the rapidly fatal effects sometimes produced in the hot, damp, malarious season. Death was due to the pulmonary engorgement, accelerated by the fibrinous coagula in the right side of the heart and pulmonary arteries. The overwhelming action of the malarial poisoning accounted for the

rapidly fatal result. The patient was a healthy, temperate man, his organs were sound, and he had not been ill for months before this attack. The second paroxysm proved rapidly fatal, despite all attempts to relieve him. Quinine and stimulants were freely given by mouth and injection; warmth and revulsives were also freely applied. This case occurred at the most trying time of the year, when the temperature was high, probably 90°, and the air saturated with moisture. He had been exposed to the sun during the greater part of the day on which he was attacked.

The following abstract of a case has just been sent to me by Surgeon S. A. Crick, of the Army Medical Department:—

"*Fibrinous Coagula in the Heart resulting from Malarial Poisoning.*—This case now appears to me to have been of this kind. When in Hong-Kong last summer, an officer (a surgeon-major) arrived there about June; he was a fine, strong, healthy-looking man, and had just come from England. Within two weeks of his arrival he was suffering from malarial poisoning, the brunt of the disease being thrown upon stomach and intestines, with a slight amount of associated intermittent fever. A state of malarial cachexia rapidly supervened, and when I left Hong-Kong, on August 17th last, he was looking extremely ill. A few days ago I received a letter from the principal medical officer at Hong-Kong, informing me that the gentleman had been invalided and left Hong-Kong on September 1st. Four days after leaving he is said to have had a sudden attack of syncope, from which all efforts of the surgeon on board failed to revive him, and he therefore died and was buried at sea. I am convinced this must have been a case similar to those observed by yourself. I believe in this case the cause of death was certified as: (1) Malarial poisoning; (2) dilatation of heart. I saw him daily at Hong-Kong, and certainly detected nothing cardiac. I think I can recall one or two cases of sudden death occurring in the course of continued fever which might probably be referred to a similar cause. I trust your remarks will stimulate medical men having to do with malarious cases to careful discrimination between ante and post-mortem cardiac and pulmonary clots."

A native student, aged twenty years, was admitted into hospital at Calcutta, on 15th April, 1870, with a sloughing portion of the integument of the leg, caused by a blow. He had been suffering from malarial fever and enlargement of the spleen for five months, a statement which was confirmed by his cachectic appearance. He was depressed and feeble, with a small and quick pulse, but no diarrhoea or fever. Stimulants with quinine and a generous diet were ordered. He remained in this condition for two days, during which time a portion of integument below the knee, of about two inches in extent each way, sloughed. On the 18th his respiration became hurried. There was slight increase of temperature, 99.4°, but it fell below the normal standard afterwards. Ammoniacal stimulants and quinine were continued, but there was no improvement. The respiration became more gasping and hurried; no cardiac murmurs were heard, the breathing became more gasping, and he died at midnight of the 20th. Post-mortem examination: Liver normal; spleen much enlarged. The lungs were hypostatically congested, a portion of the lower lobe of right lung was consolidated, but there was no other disease. The heart was healthy, but it contained a firm, fibrinous, decolorized coagulum, extending from the right auricle, where it was reddish in color, into the right ventricle, where it was straw colored; thence into the pulmonary artery, where it was firm and moulded like the branches of a tree, in the sub-

division of the artery. The left ventricle, auricle, and aorta contained similar coagula. There was no other disease except the patch of gangrene of the integument below the knee.

A gentleman aged forty-five to forty-six, who had returned from a tropical and malarious region, came under my observation last year. He was cachectic and weak, having suffered from dysentery and fever. He suffered considerably from evidences of malarial poisoning, and frequently from intense neuralgia. There was nothing to indicate liver abscess during life; indeed, the history of the case spoke of liver contraction. He died a few days after his arrival. I found him on March 5th suffering great abdominal pain. Pulse quick and feeble; skin clammy; temperature subnormal; breathing hurried and shallow. This rapidly became much worse, and continued until death, at 10.30 P.M. on the 6th. The lungs after death were found pale and emphysematous, but hypostatically congested at the base, otherwise normal. The pericardium contained a considerable amount of serum. The heart was normal, but the right auricle and ventricle were nearly filled with firm decolorized conglomulum, which extended into the pulmonary artery and its minute ramifications. The left cavities of the heart were empty; the heart itself and its valves were normal. There was no sign of dysentery; the intestines, kidneys, and spleen were normal. These appear to me sufficient to illustrate the pathological condition to which I have referred. In a future communication it may be well to illustrate the effects of thrombosis arising from such causes, as it occurs in the left cavities of the heart or their arteries.

A Mirror

OF

HOSPITAL PRACTICE,

BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Procnium.

ST. THOMAS'S HOSPITAL.

A CASE OF ILIO-FEMORAL ANEURISM, WITH GANGRENE OF THE FOOT, DEVELOPED IN A PATIENT SUFFERING FROM CARDIAC DISEASE AND ALBUMINURIA, AND IN WHICH LIGATURE OF THE EXTERNAL ILIAC ARTERY AND AMPUTATION OF THE THIGH WERE PERFORMED.

(Under the care of Dr. BRISTOWE and Mr. SYDNEY JONES.)

H. F.—, aged twenty, a female, married, was admitted under the care of Dr. Bristowe on May 5th, 1882, when the following history was obtained:—Her mother suffers severely from rheumatism, but with that exception the family is a healthy one. The patient had an attack of rheumatic fever when fifteen years old, and has been subject to rheumatism since. Her heart has been affected for many years. The present illness dates from soon after her confinement, ten weeks ago. It began with swelling of the right leg, then her foot became dead, and this loss of feeling extended up to the knee; the foot then became dark, and feeling returned in the upper part of the leg. Three weeks before admission the foot was

“blackish-purple” in color, and very painful, the pain, which was of a shooting character, extending up the leg. Latterly, the pain has been less, and the foot less purple. Has been perspiring a good deal lately, and for two nights has had a sharp pain in the left side of her chest.

On admission, the condition was thus described:—The patient is exceedingly pallid, much freckled, conjunctivæ anæmic, looks ill, and complains of pain in the right foot. The anterior part of the right foot is gangrenous. There is a distinct line of demarcation running across the foot, a little posteriorly to the roots of the toes. In front of this line the skin is turning black, and is quite black in places; there are a few vesicles filled with serous fluid in the dorsum; it is not sensitive. Posteriorly to this line the skin is hard and brawny; sensation is present. The leg is quite warm; the knee is contracted, and cannot be extended fully. In the right groin in the situation, and in continuation with the common femoral artery, there is a pulsating tumour about the size of a small walnut; there is a systolic thrill felt over it, and on auscultation there is a loud systolic murmur, which can be traced down the artery nearly as far as the knee. The artery can be felt pulsating for two or three inches below the tumour. Chest expands fairly well; some episternal pulsation, and a little pulsation in the sides of the neck. Heart: apex beats in the nipple-line between the fourth and fifth ribs; dullness extends to half an inch to the left of the sternum, and upwards to the third rib. At the apex a loud systolic blowing murmur conducted into the axilla, and all over the cardiac area. No murmur at base. Pulse 101. Lungs resonant, breathing vesicular; abdomen retracted, liver dullness normal; tongue dryish, furred, white; bowels open; appetite bad; sleeps poorly; mind clear. Urine, sp. gr. 1022, acid, contains pus and albumen. Temperature 101.4°.

May 9th: The specific gravity of urine only 1005; no casts in albumen. Patient feels drowsy, apparently in less pain.

May 10th: Mr. Sydney Jones saw the case in consultation with Dr. Bristowe, and gave as his opinion that the tumour in the groin is a fusiform dilatation of the femoral artery; it is very painful and tender. The anterior part of the foot is black and cold, and the line of demarcation between the gangrenous and living parts is well marked; there is little pain in the foot. The patient says that she noticed the aneurism a week after her confinement, but she varies a good deal in her statements as to the time.

May 24th: The aneurismal swelling changes considerably, being nearly four times as large as it was on the 10th; it is somewhat irregular in shape, hard, and tender, and the pulsation is less marked in it, and there is no pulse to be felt in the arteries of the leg. The foot remains in about the same condition, whilst the temperature of the right thigh is two degrees higher than that of the left. She complains of tenderness in the knee, and is light-headed.—25th: General condition remains the same; there is some pulsation in the anterior tibial. Pulse 115.—26th: Delirious for the last twenty-four hours. Had a very bad night. Complains of general tenderness. No change locally. Bowels confined.

June 1st: Patient still light-headed, has picked the epidermis off her foot and ankle, and whines very much. The swelling in the right groin is increasing.

June 2nd: Transferred to a surgical ward under Mr. Sydney Jones. The line of demarcation in her right foot has deepened, the aneurism is the size of a closed fist, and occupies the whole of Scarpa's triangle, passing upwards under Ponpart's

ligament. She has become much more querulous, and is in a semi-idiotic condition, with a great deal of pain in the aneurism. It is urgently necessary for something to be done. There is gangrene of the foot, presenting a tolerably distinct line of demarcation; there is a large inguinal aneurism on the same side rapidly increasing in size, extending above Poupart's ligament, and involving quite the upper third of the thigh. The merits of the case were considered in all directions, and it was decided that the best course to pursue was to put a ligature upon the external iliac, and then to amputate the thigh in the lower third. This Mr. Sydney Jones proceeded to do. Ether having been administered, the external iliac artery was reached by an incision of curved linear form, extending from a little behind the anterior superior spine of the ilium to a point corresponding to the middle of Poupart's ligament; the structures were carefully divided in a direction drawn to the inner side, and the exposed artery ligatured with a thick catgut ligature. A small drainage-tube was placed in the wound, which was closed by alternate silk and catgut sutures. The operator then amputated the thigh at the junction of the middle and lower third, a long anterior skin and muscle flap, and a short posterior. The latter made by transfixion. The flaps were united by alternate silk and catgut sutures. Drainage-tubes were used. The operations were carried out with strict antiseptic precautions, the abdominal incision having been dressed before the amputation was commenced. The patient suffered a good deal from shock, especially when the bone was divided.—3rd: She slept for half an hour after the administration of one-sixth of a grain of morphia subcutaneously, and dozed a good deal afterwards. She had a quiet night. There has been no sickness. Pulse 110, small.—4th: The patient took beef-tea well until the evening; she then complained of nausea. She was quiet, and progressing favorably. The stump was dressed in the evening, and the silk sutures removed.—5th: She seemed more sensible, and was not so querulous.—On the 6th and 7th she was more drowsy, and inclined to delirium; she was not taking nourishment well. Pulse small and weak.—9th: The wounds were dressed, both looking well; the abdominal incision had nearly healed. The patient said she felt better. She was taking plenty of nourishment.—10th: The urine was rather dark when passed early in the morning, and quite pale when passed later in the day. Pulse 130; respiration 40.—12th: The patient was not quite so well. She took her food less readily, and complained of pain across the epigastrium, for which a linseed poultice was applied. Pulse 108; respiration 36; urine, sp. gr. 1015; albumen 1.13.—13th: The patient was very restless in the morning, but was quieter towards evening. Pulse in the morning, 168.—14th: She had been very restless all night, and was breathing very rapidly, 50 per minute. She complained of a feeling of sickness, and of pain in the chest. Pulse extremely quick (?210).—15th: Looking pale and pinched, hands are cold. Takes her food fairly well, and is not so restless, slept a good deal during the night. Complains of a good deal of pain in the abdomen, which is considerably distended. Antiseptic dressings changed for chlorinated soda lotion, no pus comes from the wounds, which look inactive.—16th: Slept fairly well last night after an injection of morphia, looking rather more pinched this morning. Hands very cold, and pulse so small that it cannot be counted. Respiration very rapid and shallow, from 36 to 40 per minute. Takes milk fairly well, but refuses wine, which she says increases the pain in the throat, of which she is now complaining. Bowels acting naturally.—

17th: Patient died quietly whilst asleep at 9.30 A.M.

The temperature, which on admission was 101.6°, rose the same evening to 102°. Although higher in the evening than in the morning, it did not again exceed 101.6°, until the evening of the 9th, when she had her highest recorded temperature, 104.4°. After this date the record shows a hectic character, being three to four degrees higher in the evening than in the morning, falling slightly lower from night to night until the evening of the 30th, when it was again 101.6°. Next day, however, it rose from 98.8 A.M. to 103.6° P.M., without apparent cause, falling on the 31st to 99°, and only rising to 101° P.M. On the morning of the operation, June 2nd, it was 98.8°, and in the evening 98°. After the operation the course was more erratic.

106° at noon.

The post-mortem examination, made by Dr. Haddon fifty-three hours after death, showed, in addition to the local condition, considerable visceral disease. Body much emaciated, commencing putrefaction. Left pleura adherent all over by old adhesions; right contains ten ounces of blood-stained fluid. The left lung very oedematous; right fairly normal. Pericardial sac closed by old adhesions, which are oedematous. Heart very flabby and soft from decomposition. Left ventricle hypertrophied; the free end of the mitral valve was soft and thickened, there were distinct vegetations on the auricular aspect of the valve, exact condition obscured by post-mortem change. No peritonitis. Liver soft and decomposed; no infarcts. Spleen large, contains numerous infarcts, hard, decolorized, and undergoing contraction. Kidneys: capsules not adherent; in the cortex were numerous fairly old infarcts, some typically wedge-shaped. In the right iliac fossa the ligature was found loose, and a drop or two of pus were seen near this spot. The right common iliac was filled with dark, soft, very slightly adherent clot, nowhere decolorized, and showing no signs of organization. The clot also extended into the internal iliac. The vessel was evidently ligatured at a spot an inch and a quarter from the aneurism, for here the course of the artery was interrupted, and not to be found; just above the artery was filled in (as before mentioned) by soft dark clot, but below the lumen of the vessel was much contracted, and contained partially decolorized and organized coagulum. The aneurism itself was diffuse, and without defined walls. It bulges from the inner side of the femoral at its commencement, and to a less extent from the end of the external iliac. The aneurism was about the size of a small orange. Externally there was a layer of white, firm, laminated clot; towards the centre the clot was only partially decolorized; whilst quite inside, and filling in the cavity, was some blood, apparently recent conglum, very slightly adherent to the middle layer. The corresponding femoral artery was apparently healthy, and showed no signs of degeneration. During the removal of the vessel with the aneurism an abscess was opened, from which two or three teaspoonfuls of blood-stained pus escaped; the site of the abscess was the iliac fossa, just above Poupart's ligament; it was external to the artery, and, on further examin-

ation, was found to burrow downwards, still lying external to the aneurismal sac, and in no way communicating with it.

LARGE AXILLARY ANEURISM; LIGATURE OF THE SUBCLAVIAN ARTERY; RECOVERY.

(Under the care of Sir Wm. MAC CORMAC.)

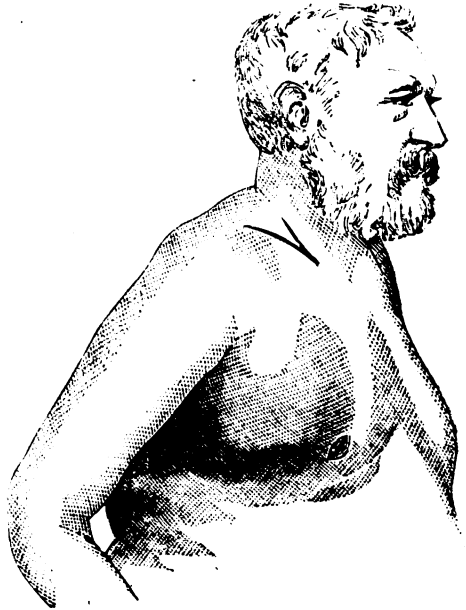

For the following notes we are indebted to Dr. W. A. Duncan, house-surgeon.

The patient, a man aged forty-nine years, was admitted on Aug. 21st, 1882. He had been healthy, and had followed the occupation of a carpenter. He was of very stout habit of body and florid complexion. Formerly, for six years he had been a soldier, and served during the Crimean campaign. At Scutari, in 1856, he suffered from an attack of inflammation of the lungs, for which he was bled and cupped. In 1857 he had a chancre and bubo, and some weeks later his body was covered with a rash. He remained well until 1876, when he strained his right arm at his work, and lost the use of it for a time. The power was gradually regained, but a small lump about the size of a walnut was soon discovered in the right axilla. Of this he took little notice, as it occasioned him but trifling uneasiness. A month before admission he again strained the arm, and the tumour now began to increase much more rapidly, especially during the week previous to admission; the skin over it became ecchymosed in places, and the man suffered some pain and numbness down the arm, which became considerably swollen.

When he first came under observation at the hospital a large pulsating swelling occupied the antero-lateral aspect of the chest. It could be traced up beneath the pectoral muscles as far as the second portion of the axillary artery. The brachial artery was apparently not involved. The tumour filled the armpit, pushing the arm outwards and the shoulder upwards. Behind it reached to the posterior fold of the axilla. It reached forward as far as a vertical line drawn from above the centre of the clavicle to the nipple; its lower limit corresponded to a horizontal line a little below the nipple. The tumour was soft and rounded, pulsation strongly distensible. A bruit could be heard over the posterior half. The tumour was freely movable over the deep structures in an antero-posterior direction and the skin over it was nowhere adherent. The pulsation was stopped, and the sac partially emptied, on pressure upon the subclavian artery. The radial pulse was weaker and the arm cooler on the affected side. Urine normal. Heart sounds feeble, no murmur audible.

As treatment by pressure was clearly inapplicable, and speedy interference desirable, the ligature of the subclavian artery was determined upon. The operation was performed on August 24th. An incision was first made two and a half inches long parallel to, and corresponding with the central portion of, the clavicle and half an inch above it. From the inner extremity of this wound a further incision was made obliquely upwards along the outer border of the sterno-mastoid muscle. By this means great additional space was gained. A large external jugular vein, much distended, lay in the way, and as it impeded the further steps of the operation, it was divided between a double ligature. The omo-hyoid muscle was then exposed after a little dissection, and afterwards the last cord of the brachial plexus, close below which the artery could be plainly felt and seen. The sheath was carefully opened, and a thread of thick catgut passed round the vessel, taking care to disturb it as little as possible. The high position of the shoulder, and the fatness of the man, made the

wound a very deep one, but the operation was quickly completed without much difficulty. No vessel required ligature except the external jugular vein. There was practically no bleeding. The wound was washed out with carbolic solution (1 in 20), and a large drainage-tube passed to the deepest part, the edges were brought together with sutures, and an antiseptic dressing was applied. The right arm was swathed with cotton-wool, and kept in place by a flannel bandage.

After the operation the patient was sick several times, and complained much of thirst. Some pain and numbness were felt in the limb, but the temperature did not fall. The right pupil became smaller than the left.

On August 27th, three days after the operation, the wound was dressed for the first time, the dressing contained only some serous discharge. The wound appeared to be well united. The drainage-tube and all the sutures were removed.

On August 31st, seven days after operation, the wound was redressed; there was no discharge, and the cicatrization appeared almost complete; the antiseptic dressing was left off. The patient now felt quite comfortable and was going on well in every respect. The aneurismal sac was steadily contracting and there had been no return of pulsation in it.

The temperature reached 100° F. the day after the operation, but for the most part it varied between 98.4° and 99.4°; the pulse was usually about 80. The patient's only complaint was at first of the heat and inconvenience of the dressings about the neck. The wound united by first intention, except where the drainage-tube lay, without visible reaction, and as soon as the tube was removed, this channel closed directly; the catgut noose around the vessel must have been completely absorbed.

On October 4th, forty days after operation, the notes report an uninterrupted improvement; the large aneurismal sac had diminished a half in bulk and was quite hard. It was believed faint pulsation could be felt in the brachial; but neither in this artery nor those of the forearm could any pulse wave be afterwards felt.

The man since he left the hospital has presented himself from time to time and his condition leaves nothing to be desired. The woodcut, copied from a photograph kindly taken by one of the St. Thomas's students, Mr. West, represents the dimensions of the swelling and the position of the incision made in order to reach the subclavian artery.

BARROW HOSPITAL.

CASE OF COMPOUND FRACTURE OF SKULL WITHOUT HEAD SYMPTOMS.

(Under the care of Mr. WILLIAMS.)

For the following notes we are indebted to Mr. R. Heelis, house-surgeon.

Robert A—, aged fifteen, was admitted on Oct. 20th, 1882. Three hours before admission he was struck on the right forehead by a tipping truck, in rapid motion, and thrown some distance. He was insensible for about five minutes, and then got up and went on with his work. He applied to the hospital at midday as the wound seemed serious.

On admission there was a small oblique wound one inch above the upper and outer angle of the right orbit extending to the bone, which was bare for about half an inch beneath the lower edge of the wound. This bare bone was bounded above by a sharp, free edge of crescentic shape, which could be felt through the skin, its extremities being above and beyond the ends of the external wound; the bone above this was depressed. The patient walked steadily and was quite sensible; the skin was warm and pupils equal and dilated. He was put to bed, and the wound syringed out with carbolic lotion, one in ten, and dressed with dry salicylic silk. The dressing was changed on the 22nd, 29th, and 31st. On the 29th the wound was scabbed over, and on the 31st only a small granulating sore was left, and he went out on that day. During this time he had no headache or delirium and slept well. His temperature on the first and second days was 99.2° and 99°, afterwards normal. The pulse was 84 on the same days and regular; afterwards it was less frequent.

When seen by Mr. Williams a few days ago the edge of bone could still be felt. He suffers from headache occasionally when at work.

CASHEL UNION HOSPITAL.

CASES OF THORACENTESIS.

(Under the care of Dr. LAFFAN.)

CASE 1.—M. D—, aged twenty-six years, a female servant, was admitted in April, 1880, with acute pleuritis on the right side, and bronchitis of the left. The right side of the thorax was three inches larger than the left. Pulse 120; respiration 60. On April 28th dyspnoea became urgent. Thoracentesis was performed, and fifty-six ounces of serum were withdrawn. The pulse at once fell to 80, and the respiration to 30. The notes state that on May 1st the pulse was 116, respiration 36, and the temperature 105.8°, and that the right lung, where previously no sounds were to be heard, was now like the left, the seat of universal râles. The patient ultimately became quite well.

CASE 2.—W. D—, aged five years, was seized with pleuritis of the left side on June 10th, 1882. He came under observation on August 12th, at which time the entire left side was dull, and the apex of the heart-beat between the fourth and fifth right ribs. The patient's general condition

was at the lowest ebb. Paracentesis was performed on that day, and about twelve ounces of healthy pus were removed. A piece of lint was inserted into the wound, and removed from day to day to allow free exit for the discharge, and small doses of coca were given internally. A few days afterwards, on August 24th, the pleura was injected with a solution of tincture of iodine. The next day, and for some days afterwards, he was seized with cough and symptoms of extreme debility, which seemed connected with the infection. He, however, gradually improved; the bronchitis continued. A small purulent discharge persisted from the pleura, and coca, syrup of iron, and supporting treatment were administered until Oct. 12th, when he expectorated per mouth for three successive days a large quantity of pus, similar to that which came from the side, after which all cough left him. The discharge from the pleura ceased, and he made more rapid strides towards health and strength.

On Dec. 7th there was a mere moisture from the wound. His health was perfect, and the chest signs were normal. The wound was to be closed. The girth of the chest on the right side was 16 in., and on the left 15½ in. This patient was reduced to the last stage of asthenia, and his recovery was something surprising, even having regard to the greater chance of patients of his age. The sudden and great expectoration appears to be due to perforation of the lung; no stethoscopic signs were detected, and the fact that this at least did no harm is in keeping with the records of similar occurrences.

CASE 3.—D. N—, a female aged twenty-three years, came under observation on July 10th last. Her illness dated from February 14th preceding. On admission the left side of the chest was completely dull. It was opened on the 11th between the sixth and seventh ribs; with the aid of the aspirator thirty ounces of serum were drawn off. She was able to move about in four days. On December 7th her state was as follows. The left side of the chest was normal on percussion in front, and slightly deficient in tone behind. The circumference was 16 in. on the right side, and 15½ in. on the left. There was no signs of the presence of any fluid. The appetite, sleep, menses, and all other functions were normal.

CASE 4.—J. S—, aged twenty-five years, came under observation in 1880, for effusion in the left pleura. The dullness was universal, and the urgency of the symptoms called, as in the previous cases, for operation. The left pleura was opened in the usual place, and about sixty ounces of serum were withdrawn by a small needle of the aspirator. Some fluid was again effused, but this was absorbed, and the patient recovered. Some of the patient's brothers had died of phthisis, but he continued well.

CASE 5.—T. D—, aged twenty-eight years, was first seen on the 1st of June, 1882. The entire left pleura was filled with fluid; the apex of the heart beat between fifth and sixth right ribs. There was a history of his having suffered for five years from the disease. He had been under the care of three physicians successively, who took the case for phthisis. The chest was opened with a large needle of the aspirator between the eighth and ninth ribs, and one inch to the left of axillary line. Three gallons of a serous-looking fluid were withdrawn. The patient made an uninterrupted recovery, and now pursues the active duties of a cattle-dealer, to which he has transferred his services from his former and less onerous post of land steward. It is intended to publish the case in *extenso* on account of many points of interest.

SEAMEN'S HOSPITAL, GREENWICH.

CASE OF PERNICIOUS ANEMIA.

(Under the care of Dr. CARRINGTON.)

For the following notes we are indebted to Mr. E. Penny, M.B. Lond., house-physician.

Heinrich L—, aged twenty-one, a Norwegian sailor, was admitted on March 2nd, 1882. As he spoke no English, a clear history could not be obtained; but it appeared that he had been at Wilmington, Mexico, in the winter, and had had ague there.

On admission he was very anæmic, and became rapidly worse. Towards the end of April he presented the following symptoms:—Extreme pallor and smoothness of the whole cutaneous surface; mucous membrane of the mouth and eyelids almost colorless; rapid and excitable cardiac action, often causing much distress by the violence of the beating; no distinct cardiac murmur, but a slight systolic roughness at base; respiration on the slightest exertion deep and hurried; a few moist sounds generally through the lungs; subject to syncopic attacks, during which the pallor became more intense, and the breathing very distressed. He complained frequently of pain in the epigastrium, while extreme tenderness with slight swelling of the lower part of the right thigh came on. There was also very slight œdema about the ankles; hæmorrhage into the retina took place, while the blood showed extreme diminution of red corpuscles without increase of white ones, the former being of very abnormal shapes and sizes. Examination of the patient caused much distress, and often alarming attacks of syncope towards the close of life, so that it was impossible to investigate the case very closely. Although he seemed generally tender and resented disturbance in any way, no distinct tenderness over the bones was made out.

On April 29th Dr. Stephen Mackenzie examined the patient, the following being the result of his observations. Numerous superficial retinal hæmorrhages, some flame-shaped, some fan-shaped, and others round, and a few white patches; discs swollen; edges indistinct. Microscopic examination of the blood showed the red corpuscles much reduced in number, variable in shape, some tailed, some elongated, and others very small; they showed no tendency to form rouleaux, though congregating in clusters; the smaller corpuscles were not deeper in color than the larger normal ones; no granular corpuscles.

During the patient's residence in hospital his temperature varied generally between normal and 100° F., being often lower in the evening than in the morning, and rising at times as high as 101°. Diarrhoea occasionally came on. He took nourishment well the whole time. From March 22nd to April 19th he took, every four hours during the day, one-thirty-second of a grain of arsenious acid, combined with ten grains of sulphate of quinine.

On April 19th the arsenic was raised to one-twenty-fourth of a grain in a dose, but as very troublesome vomiting followed, the medicine was discontinued on April 22nd. Some days before death the patient complained of pain in the left chest, which was followed by slight effusion in the pleural cavity; his breathlessness became more marked, so that he could not rest in the recumbent posture; vomiting returned about the same time.

The patient died on May 4th after a syncopic attack, in which the breathing became extremely distressed and rapid. With the exception of a single attack of epistaxis, no loss of blood took place during his stay in hospital.

Necropsy.—The body was not at all wasted; there was much fat in the abdominal walls and omentum. The heart was flabby and relaxed, containing clots, uniformly of a dark-amber color. On section, the inner third of the cardiac wall was very pale, while the outer two-thirds showed thickly scattered ecchymoses. The pericardium contained three-quarters of a pint of clear fluid; there were some ecchymoses beneath the visceral layer of membrane. A considerable amount of clear effusion was found in both pleural cavities, and a patch of recent lymph at the left base. The liver was pale; spleen soft, but not enlarged; kidneys pale, showing points of ecchymosis here and there. The cancellous structure of the sternum and vertebræ seemed normal. The swelling of the thigh was due to œdema, apparently caused by venous thrombosis.

ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

OBSTRUCTION OF THE ABDOMINAL AORTA BY CLOT; GANGRENE OF LEGS; DEATH; POST-MORTEM EXAMINATION; REMARKS.

For the following notes we are indebted to Mr. A. M. Sheild, house-surgeon.

Mary F—, aged thirty-six, married, was admitted on Nov. 1st, 1882. She was a spare, pale, anxious-looking little woman, of a patient, quiet, disposition. Pulse 136, weak and irregular, temperature 100°, tongue red and glazed, bowels confined, urine acid, lithatic, no sugar, a little albumen. Action of heart irregular but no bruit to be heard. Skin covered with acid, sour-smelling sweat. Abdomen discolored from the use of mustard plasters. The right foot and lower two-thirds of the leg were gangrenous. The skin had lost its elasticity, was dusky red and mottled with purple. Over the heel and on the sole of the foot were sanious black bullæ, the toes and anterior part of the dorsum of the foot were dry, shrunken, and the color of tallow, contrasting with the black hue of the matrices of the nails. There was absolute loss of motion and sensation in the affected parts, which felt cold and dead. The parts near the upper limit of the gangrenous process were very painful, but there was no emphysematous crackling, or evidence of rapid advance of necrotic action. The left foot was cold and numb, the toes were a little dusky, and sensation was greatly impaired. She could move the leg, however, freely. No trace of a pulse could be felt in either femoral artery. The abdominal aorta pulsated violently to a little below the umbilicus; here all pulsation ceased. A slight bruit could be heard with the stethoscope, about two inches above the umbilicus, over the aorta, but there was no evident dilatation of the vessel. No bruit could be heard over the thoracic aorta. There was some abdominal tenderness, especially in the right iliac fossa and left hypochondriac region.

The following history was obtained:—The patient had rheumatic fever at the age of seventeen; ever since then has been "a martyr to the rheumatics." Has had four children and two miscarriages. The last child was born in May; she had an easy labour, and was soon well and about again. There was no history of syphilis. For the last fourteen days she has had to keep her bed with pains in the body and down the legs. On the morning of Oct. 29th she found her right foot very painful and numb; the left foot also suffered, but not to the same degree. Declares that at that time she could move both her limbs easily. From this date to the time of admission she has been getting steadily worse.—Nov. 2nd: She slept badly. Pulse 130; temperature 101°; other condi-

tions much the same. Takes her nourishment well. Bowels freely open.—4th: The gangrene is extending slowly on the right side; it has now reached the knee. The left foot is now evidently gangrenous. Pulse 130; temperature 101°.—6th: Had a bad night; this morning is apathetic, and very drowsy. Pulse 140; temperature 104°. She died quietly at about 11 A.M.

Treatment.—This merely consisted in applying warmth to the affected limbs, supporting the strength by nutritious diet, and giving small doses of opium at night to alleviate the pain.

Necropsy, about twenty hours after death.—The heart and lungs were fairly normal. There was a slight fibrous thickening of the mitral valve, but no granulations or ante-mortem clot. On following down the aorta these curious appearances presented themselves: The arch of the aorta was to the touch and naked eye normal. On the posterior part of the thoracic aorta, just above the diaphragm, was a small, tongue-shaped, firm, pinkish, fibrinous clot. This was quite adherent to the wall of the vessel, which in this situation presented a wheal-like elevation, fibroid to the touch, and having the endothelial coat over it roughened and altered. A little lower down was another small patch of disease; this was calcareous, and seemed of older date than the one first mentioned. The coeliac axis and its main branches were blocked by firm, adherent, fibrinous, somewhat stratified clot. This projected a little into the aorta, which here again presented a thickened opaque condition of its lining membrane, feeling in one spot gritty and calcareous. Just above its bifurcation the aortic tube was completely blocked by a firm clot, having its conical end of a gelatinous consistence and pink color, and projecting some little way upwards. The clot quite filled both common iliac arteries; the internal iliac and external iliac vessels were also completely obstructed. The whole clot was stratified, and very adherent to the intima of the implicated vessels. Near the junction of the right common and internal iliac vessels it was most decolorized and firm, greyish-white, and adherent, as though this was the oldest part of it. The vessels of the brain seemed healthy. There was nothing worthy of note in stomach or intestines. The right kidney was small, and there was a slight puckered cicatrix on its surface, to which the capsule was adherent. The spleen was enlarged, its capsule thickened, and it presented some pale wedge-shaped patches near the surface, as though the result of old embolic processes. The liver was enlarged slightly; there was one small wedge-shaped patch of evidently old origin on its surface.

Remarks.—Complete obstruction of the abdominal aorta by clot is sufficiently interesting to justify such a case being fully recorded. A number of such cases may be found related in Sir James Simpson's works, dependent, however, upon the puerperal state. Cases are also recorded in Vol. xxiii of the Transactions of the Pathological Society; one of them bears in its results a close resemblance to the one now related, the aortic tube being blocked close up to the origin of the renal vessels. The chief point of interest in the present case is the nature of the arterial degeneration, which evidently caused the blood to clot. Is was unlike ordinary atheroma in the absence of distinct implication of the aortic arch, the age of the patient, and the evident mischief to the endothelial layer of the inner coat. The primary clot was, doubtless, the small one upon the wall of the thoracic aorta; here the endothelium being altered and abnormal, caused the blood, which must have had a preternatural tendency to fibrinous excess, to coagulate upon it. The coeliac axis seems next

to have got plugged, and from the conical projecting end of the coagulum that filled it, another clot got washed away by the impact of the powerful stream of blood in the aorta into the right common iliac vessel. Here it lodged at the bifurcation of the common iliac artery into its external and internal divisions, completely obstructing it, and also causing thrombosis to take place, and so secondarily block both the left common iliac artery and the aorta itself. The oldest portion of clot below was certainly in the right iliac vessel, and the clinical history of severe abdominal pain, followed by sudden gangrene—first of the right, then of the left lower limb—would support the view above advanced. The origin of the clot and the primary seat of its arrival in the iliac vessels are very interesting and open to several explanations. It is also worthy of remark that but slight indications of mischief showed themselves in the great abdominal viscera, though the great artery, the coeliac axis, was quite firmly plugged.

LEEDS INFIRMARY.

ACUTE PERICARDITIS WITH EFFUSION; PARACENTESIS PERICARDII; RECOVERY; REMARKS.

(Under the care of Dr. CLIFFORD ALLBUTT.)

FOR the following notes we are indebted to Mr. J. F. W. Silk, M.B., house-physician.

J. D—, aged twenty years, draper's assistant, was admitted on Dec. 23rd, 1881, and discharged well on May 18th, 1882. The following notes are abstracted verbatim from the clinical report of Dr. Barra, then house-physician: No family history of rheumatism. He had rheumatic fever six or seven years ago, when he was laid up for five months. He was last at work on Dec. 19th. On the 20th he took to his bed on account of pains in the joints, especially the hip and knee. The onset was quite sudden on the morning of the 19th, but there was no rigor. He came to the hospital on Dec. 23rd, looking very ill and in obvious pain, saying he was suffering from acute rheumatism. When seen in bed he still complained of pain, but in an indefinite manner. He had scarcely the aspect of acute rheumatism; there was a want of helplessness, and the limbs were freely moved about. There had been no diarrhoea; no spots; joints all free from any physical change; tongue brown and dry in centre; heart sounds clear. Temperature 99° (after a warm bath). Ordered twenty grains of salicylate of soda every two hours.—25th: Morning temperature 103°; evening temperature 104°. Still taking salicylate every two hours, but troubled with vomiting.—28th: Temperature still running at a mean of 103°. Salicylate ordered to be stopped.

Jan. 1st, 1882: Slight diarrhoea yesterday. Complaints of tenderness on pressure in both iliac fossae. Copious eruption of sudamina. During last thirty hours has been taking twenty grains of salicylate of soda; there has been slight delirium in consequence. Temperature never fell, and salicylate is now stopped.—6th: Temperature 102°. Great dyspnoea this morning. Very distinct pleuritic rub at right base. General aspect bad and obscure. Mind clear. Taking opium (one grain every four hours) for relief of pain.—9th: Temperature 101.4°. Last night's temperature 105°. He was sponged with tepid water, and all the bed covering was removed. The temperature fell to 102° after thirty minutes' exposure. This morning there was great dyspnoea, and a general pleuritic rub over the whole of the right side of the chest. The general condition is not so good.—12th: better. Respiration 48; pulse 84. The pleuritic rub

has disappeared, so far as the anterior part of the right chest is concerned.—14th: Delirious throughout the night. This morning temperature 101°; pale; pupils dilated; mind clear. There is more dullness at the right base of an indefinite character, with very obscure auscultatory signs, except distinct pleuritic creaking. The abdomen is a little tender. Spleen not felt. Bowels acting; no diarrhoea. Respiration 40; pulse 80. Tongue moist. He is now taking three or four pints of milk in twenty-four hours, with eight ounces of whisky.—17th: Temperature at 7.30 last night 104.5°; after sponging for twenty minutes it fell to 101.4°. Has passed a restless night. Had three grains of opium, but slept only two hours. Now lying on the left side. No change in the physical condition of the right chest.—23rd: There has been steady improvement during the last four or five days. This morning he is pale, and breathing rapidly; pupils not dilated. Not in any great pain, but a little discomfort in breathing. Heart: Cardiac dullness much increased. It begins at the third rib, and extends down to the sixth, and is much increased to the right of sternum (absolute dullness); apex not localized; distinct friction fremitus felt over the upper part of dullness. On auscultation friction sound distinctly heard over the upper half of the dullness, the systolic portion of which is double. Pulse 130; temperature 99°.—evening temperature 100.6°.—29th: Cardiac dullness about the same as on the 23rd. Friction sound unaltered at base. General condition about the same. Pulse 142; temperature 99°; evening temperature 101°.

Feb. 2nd: Pericardial effusion rather increased than otherwise. The præcordial region has a full distended look, there being a want of interspace markings. The absolute dullness begins now almost at the second rib and extends down to the seventh laterally; the dullness measures at the level of the fourth rib eight inches. Sounds obscure and distinct. No friction sound heard. Patient is pale and anxious. To-day, for the first time, a change in the abdomen is noticed. The epigastrium is full and tender, and dull on gentle percussion. Edge of liver is easily felt at about the level of umbilicus. Temperature 100°; pulse 128; evening temperature 101.6°.—4th: Patient better. Pulse, although rapid, is much steadier. Breathing 36, much freer. There is some slight improvement in physical signs. The cardiac dullness is not so great. Epigastric swelling and tenderness gone. Temperature 102°; pulse 152.—5th: Intense pain in back of chest during the night, with great dyspnoea. Sweating profusely. This morning he is better. Temperature 101°; pulse 142; respiration 52. The præcordial dullness is a little increased.—7th: General and local condition about the same. It is evident that he cannot hold out much longer if present condition continues. At 4.30 P.M. aspiration of the pericardium was performed by Mr. Ward, the house-surgeon, according to the plan followed by Dr. Clifford Allbutt and Mr. Wheelhouse in a similar case under the former's care about ten years ago. The fine aspirator needle was entered obliquely in the fourth left space, two inches and a half from the middle line, and pushed upwards and backwards towards the middle of the right scapula until a cavity was clearly entered at a depth of about an inch and a half. Only about an ounce of bloody turbid serum was drawn off (more could not be obtained). It was intended to withdraw as much fluid as possible. The patient struggled a good deal at first, but the operation did not really give rise to any special distress. Temperature 102°; evening temperature 101.8°; respiration 56.—8th: passed a good night. Says he feels much better. Breath-

(22)

ing still short (40). No marked change in cardiac physical signs.—9th: Temperature 99°; pulse 120; respiration 32.—10th: Temperature 100°; pulse 96; respiration 32.—11th: Much better. Temperature 100°; pulse 88; respiration 32. Area of cardiac dullness much less. Absolute dullness commences now at lower border of third costal cartilage, and extends downwards to sixth rib. It measures transversely at fourth cartilage (its widest part) six inches. Distinct cardiac impulse can now be seen and felt in fourth and fifth spaces. Sounds thumping and dull, but free from friction or bruit. General condition much improved. (The marked fall in pulse-rate may be due to digitalis, eighty drops of tincture per diem, which he has been taking since 5th inst. It is therefore discontinued.) He is now taking solid food, with eight ounces of whisky, and milk *ad libitum*. Evening temperature 102°.—12th: The cardiac dullness has fallen to nearly its natural size. The main increase is now to the right. Temperature 101.2°; pulse 120; respiration 32. He complains of pain in his back. There has been no difficulty in swallowing throughout. Lungs clear.—15th: Cardiac dullness continues well defined. Commences above at lower border of third cartilage and extends to sixth rib. Transversely it is limited by middle line and a point four inches to the left of this. Heart-sounds are of a thudding character. No friction or bruit. Base second sound is split. General condition improving. Temperature 99°; pulse 120; respiration 32. Pulse of no marked character.—22nd: Much better, but still pale and looking ill. No dyspnoea of importance. Cardiac dullness is still a little large and too easily defined. Temperature 99°; pulse 100; respiration 24.

March 8th: Allowed to get up for an hour. With the exception of a rather severe attack of vomiting, he continued to improve rapidly, and left the hospital on May 18th, 1882.

Remarks.—The drugs employed in the case were various, and given, with the exception of salicylate of soda, rather with the idea of combating the tendency to death than with any specific notion, and consequently have not been noted. It may be well to note that blistering was discarded. Among the many points of interest in the case, the following may be specially noted:—1 The rather doubtful rheumatic nature of the case at the commencement, and the failure of salicylate of soda to relieve. 2. The total absence of all joint affections, assuming it to have been a case of rheumatic fever. 3. A point so difficult to display in the notes, but so obvious to all who saw the case from day to day; the rapidly downward course of the case immediately prior to the aspiration, and the unaided part the operation played in saving life. 4. The comparatively rapid absorption of the effusion after the withdrawal of so small a portion of it.

NORTH STAFFORDSHIRE INFIRMARY.

A CASE OF ADDISON'S DISEASE; PIGMENTATION OF THE SKIN FROM THREE TO FOUR WEEKS' DURATION; SUDDEN DEATH FROM SYNCOPE; NECROPSY.

(Under the care of Mr. West.)

For the following notes we are indebted to Mr. G. S. Hatton.

E. P—, aged fourteen years, a young girl of no occupation, residing at Hanley, was admitted May 13th, 1882, complaining of general weakness, with pain in the epigastrium and vomiting after food. Her family history was good. The parents were both of English birth, and their skin was not unduly pigmented. So far as could be ascertained there was no hereditary predisposition to phthisis.

The patient had always lived in Staffordshire. Her mother stated that the patient had been strong and healthy as a child, and had never suffered from any illness requiring medical treatment until two years ago, at which time she became an out-patient at the infirmary for "fainting fits," and, although improvement followed, she has never quite recovered. Within the last few months she has attended in the surgical department for abscesses in the arm. Three weeks before admission she commenced to suffer from sickness after food, with anorexia, pain in the epigastrium, and general weakness, and, to quote her mother's words, "since then she has been getting a bad color." Her complexion was not at all dark until after the sickness and other symptoms commenced. "She was never a stout girl, but had lost flesh slightly." Catamenia not appeared; "a slight cough at times."

On admission the patient was thin, but not emaciated. Hair brown in color, and rather dark. All symptoms before mentioned were still in existence; she always felt cold, but did not shiver; temperature in axilla 98°. The sickness was not very troublesome while in the hospital, but the debility was extreme, so much so that she could not walk without help, and felt faint on the slightest exertion. The pulse was feeble and rapid, but quite regular; the tongue clean and moist; the bowels natural. There was no oedema of face or extremities. The conjunctivæ were perfectly white. The general pigmentation of the skin was a symptom which immediately attracted one's attention, and it varied from a light-brown to a deep bronze-color. On the arms were some three or four superficial abscesses, varying in size from a half-crown to a five-shilling-piece, and from one of these issued a scanty discharge, having the appearance of ichorous pus. The skin on the surfaces of these abscesses was deeply bronzed, but in several places where old abscesses had healed the cicatrices were almost devoid of pigment. The greatest amount of pigmentation was observed in the neck, axilla, and lumbar regions, while the skin was also very dark near the nipples and the umbilicus, also along the margin of the lips, at the angles of the mouth, and at the internal and external angles of the orbit. On the arms the color was deeper in tint over the extensors than the flexors, and while the skin over the dorsum of the hands and fingers was very dark, that on the palmar surfaces was almost of its normal appearance. The legs generally were less stained than any other parts of the body, but at the hip, knee, and ankle on either side there was some deep pigmentation, distributed as follows: In the first and last situations named, it consisted of a broad band extending transversely in front of the joint, and at each knee there were two similar bands, commencing on either side of the popliteal space and gradually becoming lost towards the patella. The popliteal space itself was but little altered in appearance. On the neck and in the axilla were some few patches of even a deeper tint than the surrounding skin, and with fairly abrupt and well-defined margins; but in most parts of the body the transition from one degree of pigmentation to another was gradual and ill-defined. In the mucous membrane of the mouth a line of pigmentation extended backward from each angle for about an inch, besides which some small brownish patches were visible with an irregular but distinct outline. A physical examination of the chest revealed the existence of slightly impaired resonance over apex of right lung; but no abnormal sounds were heard on auscultation. The respiration was shallow, and the expansion of the chest-walls deficient. The heart was not enlarged, and there was no murmur. There was tenderness in each flank and in epigastrium, but otherwise the abdo-

men seemed natural. The urine was clear and of acid reaction; specific gravity 1028; no albumen. During the week that the patient was under treatment the sickness improved, but the bronzing of the skin and all other symptoms increased. On the seventh day she died suddenly, apparently from an attack of syncope. The treatment adopted was a light but nutritious diet, and a mixture was ordered containing arsenic and iron.

At the necropsy, made twenty-four hours after death, the body was somewhat thin, but not emaciated; the rigor mortis was still present. The pigmentation was more intense than on admission. An examination of the vagina and uterus showed the mucous membrane of both of these organs to be highly pigmented, and the same condition was noticed in the peritoneum, more especially in the neighborhood of the generative organs. The right lung presented a caseous deposit at the apex, and a few patches of miliary tubercle throughout the organ. The heart, liver, and kidneys were all normal in appearance, but the spleen was congested and large. The supra-renal bodies were both enlarged, and adherent to the surrounding structures. In each gland was a cavity containing about a drachm of fluid, resembling chyle, while the gland substance itself was thickened, hard, and nodular. The weight of the two bodies was nearly an ounce, the right being slightly larger than the left. Under the microscope the fluid consisted chiefly of fat cells, pus, and granular matter. A transverse section of the gland showed what appeared to be a caseous deposit around the wall of the cavity, and a deposit of tubercle in the gland substance.

GUY'S HOSPITAL.

SARCOMA OF TEMPORAL BONE, COMPRESSING CEREBELLUM, AND CAUSING FACIAL PARALYSIS; DEATH.

(Under the care of Mr. BRYANT.)

For the following notes we are indebted to Mr. Brenton.

Augusta B—, aged ten years and a half, was admitted on July 20th, 1881, into Lydia ward. It was stated that when born she seemed healthy, but had not been so since she was vaccinated. She had had measles and whooping-cough, and disease of the knee-joint, for which her leg was amputated through the thigh. About six months before admission she complained of pain in the left clavicle, and extending up the neck. About the same time a swelling formed behind the ear, on the temporal bone. After the appearance of the swelling, she suffered from pain at the upper part of the nose, and passed several blood-clots.

On admission the child was delicate-looking; she had pediculi capitis, but neither syphilitic teeth, sores on the head, enlarged cervical glands, nor discharge from the ear. There was a hard, firm swelling, perfectly immovable behind the lobe of the left ear, and extending over the mastoid portion of the temporal bone, and the adjacent portion of the occipital. It was about 1½ by 2½ inches, and was not connected with the lobe of the ear. There was no pain in the swelling, but it was tender on pressure. The patient had throbbing pain in the occipital region. She had had no sickness, no dizziness, no pain on flexing or rotating the head, and was able to eat perfectly well. On July 24th she was seized with acute shooting pain in the occipital region, and pain down the right side of the head. She passed a bad night, constantly crying out, "Oh, my head." Her nose bled, and she vomited and afterwards became collapsed. Next day under an anæsthetic an incision was

made cutting through the sterno-mastoid. Some pus was discovered and escaped, and three pieces of diseased bone from the mastoid process were removed.

On Aug. 8th symptoms of paralysis of the seventh nerve appeared. On the 19th the right clavicle was much swollen. Patient was unable to hear with her left ear.

On Sept. 6th the wound looked well. The patient complained of great pain over the mastoid process. Facial paralysis marked. Tongue thickly furrowed, and when protruded curved to the right. Her leg from time to time was painful. On the 24th the child was much wasted; left side of face quite flat; conjunctiva reddened and thickened where exposed. The paralysis was complete. The child had difficulty in opening her mouth, and could only protrude her tongue a short way; it went rather to the right side. Both sides were wrinkled and soft, so that there was no distinct evidence of paralysis of the ninth nerve. The pupil was normal; heard with the left ear; swallowed well. On the same day, under an anæsthetic, Mr. Golding-Bird commenced an exploratory operation. An incision was made diagonally into the swelling. Some pieces of necrosed bone were taken out, and some pus was met with and evacuated. The swelling was diagnosed as a periosteal sarcoma. On the 29th she could protrude her tongue further; could close her eye nearly completely; was quieter and less ill generally. Both sides of the tongue were equal, and the tongue went out straight.

On October 19th there was considerable pain at the back of the head and neck. Unable to protrude tongue as far as formerly. Pulse weak and rapid. On the 26th a small abscess in occiput broke. Three days later there was difficulty in swallowing. Pupils were much dilated. Breath was short and gasping. Temperature was regularly taken from September 10th to October 22nd; it was normal except on September 23rd, when the morning temperature was 102°, and the evening was 101.2°—September 24th: Morning temperature 100.6°. From this time she got worse, and died at 3 p.m.

Post-mortem.—A sarcomatous growth was found filling the whole of the left post. fossa of the skull, and passing as a thin layer across the bacillar process. The left half of the cerebellum was much compressed and flattened across, as was also the medulla oblongata and nerves proceeding from it. The facial nerves were specially involved. The cerebral ventricles were much dilated owing to the exit of the fluid being hindered by pressure on the tumour. The kidneys and liver were the seat of lardaceous disease, and the lungs were a good deal congested.

WOLVERHAMPTON AND SOUTH STAFFORDSHIRE HOSPITAL.

FRACTURED CERVICAL SPINE; RECOVERY.

(Under the care of Mr. VINCENT JACKSON.)

For the following notes we are indebted to Mr. W. H. T. Winter:—

William P—, aged forty-five, fell with his neck across a rail, on June 21st, 1882. On admission to the hospital there was absence of sensibility in the arms, trunk, and legs. The arms were capable of feeble and irregular movements, but the legs were quite paralyzed. Respiration was purely diaphragmatic. The abdominal reflexes were exaggerated, and there was priapism. Patellar reflex and ankle clonus absent. There was tenderness about the fourth or fifth cervical ver-

tebræ; but no irregularity of the spines could be discovered. For some weeks there was retention of urine (the catheter being used twice daily) and obstinate constipation. On July 1st the patient had a slight attack of cystitis; and his evening temperature went up to 104°. As small quantities of urine collected in the bladder it was forcibly voided. This attack passed off in a few days. About this time sensation began to return in the legs, and motion became more powerful in the arms. Tactile sense returned slowly up the body, although the patient could not distinguish hot from cold objects. On July 14th the patient became conscious of the desire to micturate, and he could move his feet a little. From this he steadily improved. At the end of July a hard lump (callus) was found growing above the vertebra prominens. On Aug. 25th the patient was allowed to get up on the couch; and by September he was able to walk stiffly and with a little help.

On Sept. 20th he was discharged. He was able to walk very fairly, but the neck was kept rigid. Motion and sensation had completely returned. Except on the occasion referred to, the temperature was normal throughout the illness. The patient is now (December) working as a farm laborer in Shropshire.

WOUND OF THE BLADDER; RECOVERY.

(Under the care of Mr. VINCENT JACKSON.)

William A—, aged twenty-four, a carman, was loading a truck when he slipped and fell upon a trolley, such as railway porters use. The handle of the trolley tore his trousers and entered the rectum. The patient was admitted into the hospital (soon after the accident) on Nov. 18th, 1882. He complained of great supra-pubic pain and pain in the rectum. A rectal examination showed that the sphincter ani was paralyzed and dilated, and that the bowel contained blood. On passing a catheter six ounces of bloody urine were drawn off. The catheter had to be passed frequently, and pain was allayed by the free use of opium. The next day Mr. Jackson passed a silver catheter into the bladder, and introduced his finger into the rectum. He then discovered that there was a rent between the bowel and the bladder, about an inch above the prostate. A catheter was tied in, but every eight hours the patient had a desire to defecate, and passed urinous blood by the bowel. By the 20th the pain had passed off, but there was still great supra-pubic tenderness and soreness about the injured parts. The bowels were opened naturally, but the motions contained urine. There was blood in the urine drawn off from the bladder, although it daily became less in quantity. On the 23rd the urine only contained a trace of blood, and the bladder began to recover its tone, as the forcible jet of water through the catheter showed. On the 26th the patient passed water naturally, and nearly emptied the bladder. The wound seemed to heal up quickly, and the bladder muscles recovered their power rapidly, for by Dec. 1st the bladder emptied itself completely, and a very insignificant amount of urine passed per rectum. After the 4th all the urine came naturally. By the second week of December the patient expressed himself as feeling perfectly well. On the fifth evening after the injury the temperature rose to 101°, but with that exception it ranged between 99° and 100° during the first week, and 98° and 99° during the second week.

CANCERUM NASI; RECOVERY.

(Under the care of Mr. J. O'BRIEN KOUGH.)

Patrick D—, aged five, had measles in May. He became weakly, and a discharge took place

from the nose. In the first week of October the left side of the face began to swell and became inflamed. On the 8th a little hole formed on the side of the nose, on the 9th the hole was as big as a bean, and on the 10th, when the patient was brought to the hospital, there was a wound which had destroyed the left side of the nose, and was threatening to extend to the inner canthus of the eye. The left ala and the soft tissues over the left nasal bone had ulcerated away. The cavity of the nose was exposed and the destructive process was extending to the septum and the left turbinated bones and the floor. There was a black slough along the margin of the wound, and around this was a red, angry, and indurated zone. The left eye was injected and tears flowed from it. The parotid was a little tender, but the submaxillary glands were unaffected. The child's condition was deplorable. He was emaciated and exhausted, and suffered much from pain. The pulse was weak and frequent; the temperature, 103.6°. Diarrhoea was present, and the stools were dark and fetid. In a few days the left nasal bone necrosed and was removed; the cartilaginous septum and the turbinated bones were destroyed, though the vomer remained unhurt. The alveolar processes also became eaten away, and showed two of the second teeth in their beds. For twelve days the child's condition was precarious. There was a good deal of fever, but daily there was a slight improvement. The active extension of the destructive process seemed to cease on the child's admission to the hospital. At first the wound was dressed every few hours and iodoform dusted upon it. Quinine and port wine were administered to the patient with plenty of milk, and three grains of Dover's powder were given every four hours. In the third week marked improvement set in. The child was always hungry; he gained flesh; he had no pain. The wound became pink and the edges soft, and a pellicle began to form.

Dec. 14th: The child has excellent spirits, and has grown fat; but there is an unsightly hole in the side of the nose and the eye is displaced slightly downwards.

LIVERPOOL EYE AND EAR INFIRMARY.

A PIECE OF STEEL IN THE CRYSTALLINE LENS; ATTEMPTED REMOVAL; DEATH DURING THE ADMINISTRATION OF DICHLORIDE OF ETHIDENE.

WM. —, aged twenty-six, a weakly-looking man, was admitted on the morning of Nov. 21st last, suffering from a wound of the right eye, inflicted with a chipping of steel, half an hour previously. On examination the foreign body could be seen in the lens. Mr. Edgar Browne decided that an attempt should be made to extract the body. The house-surgeon, Mr. Charles Shears, on auscultation of the patient could detect no cardiac murmur, but the sounds at the base were not distinct, and it was not thought sufficient to contra-indicate the administration of an anæsthetic. Dichloride of ethidene was then given on a small flannel inhaler, and the patient came under its influence slowly but quietly. In ten minutes the man was fully under the influence of the anæsthetic, and Mr. Browne made the corneal section. Almost immediately the pulse (which had been carefully noted all through) became very feeble, and the patient very pale. The head was lowered, the tongue drawn well forwards, and artificial respiration was commenced without delay. Air passed freely in and out of the chest. Nitrite of amyl was then applied to the nostrils, and the patient was inverted. He, however, showed no signs of returning consciousness. Artificial respiration

was carried on for nearly half an hour, but without any beneficial result. Between three and four drachms of the ethidene were used.

By order of the coroner, a post-mortem examination was made thirty-six hours after death by Dr. Alexander Davidson, physician to, and lecturer on pathology at, the Liverpool Royal Infirmary. On removing the heart, it was found to be in a flabby condition, and the walls were very thin; all the valves were healthy. On the lining membrane of the aorta, one inch above the valves, and extending for some distance, small fatty patches were seen, as also on the thoracic aorta, and in one place there was the appearance as of a healed atheromatous ulcer. The heart muscle was examined microscopically, and found to have undergone extensive granular degeneration, the nuclei especially being surrounded with granules. The right lung was deeply congested.

At the inquest, evidence was given to the effect that the man died from cardiac syncope, produced by the administration of an anæsthetic to a patient whose heart was in a condition of commencing fatty degeneration, which condition could not have been discovered during life, and which certainly was not suspected in so young a man. The jury gave their verdict accordingly, adding that they thought "everything was done that could possibly be done, or that was customarily done." Since the early part of 1879 dichloride of ethidene has been largely used at the infirmary, it having been administered between four hundred and five hundred times, and, up to this present unfortunate occurrence, without any mishap. The absence of struggling, with which patients come under its influence, its pleasant smell, and the very little sickness following its administration, caused ethidene to be regarded as a specially suitable anæsthetic for operations on the eye.

EVELINA HOSPITAL.

CASE OF ACUTE CHOREA TREATED BY MASSAGE; RECOVERY; REMARKS.

(Under the care of Dr. GOODHART.)

For the following notes we are indebted to Mr. W. H. C. Newnham, B. A. Cantab., resident medical officer:—

E. S.—, aged twelve years, was admitted on Sept. 19th, 1882. Her father died at the age of forty, of some ulceration of the throat; her mother was alive and healthy. Seven other children all alive; none of them had had chorea, nor was there any history of rheumatism in the family. The patient had measles nine years ago and whooping-cough five years ago, but had not had scarlatina. It was stated that for three years the child had suffered more or less from rheumatic pains in her joints, but had never had any acute attack; these pains had existed since her convalescence from typhoid. Seven weeks before admission (after coming from Scotland to London) it was first noticed that her arms were constantly twitching; she was seen by two medical men, but in spite of treatment she got steadily worse, so that she threw herself violently about, was subject to violent screaming fits, and could not feed herself.

On admission there were very violent universal choreic movements; it was at once necessary to pad the sides of the cot with pillows. There were many marks of bruises on her arms and legs. The arms were tossed about considerably, but as there was marked motor paresis accompanying the chorea, the movements were rendered less violent than when the arms were supported. The legs were not so violently contorted; they were very cold, and she required a hot bottle to the feet.

The muscles of the face were violently twitched; there was a most sardonic grin on attempting to smile; this was almost constant when she was watched; no dysphagia; speech was almost entirely absent; patient did not answer any questions. In the first twenty-four hours she passed urine twice into the bed, and had to be watched to prevent repetitions. Urine acid, sp. gr. 1025, no albumen; considerable amount of phosphates. Lung sounds normal. Heart: Dulness not increased; apex-beat normal. At the apex was a softish, systolic murmur, also heard in the axilla, becoming much rougher at the left base. The child cried nearly the whole day, and screamed out loudly, and was much worse if her mother or any of her friends were at the bedside. In taking some milk she bit her medicine-glass, breaking it in pieces.

Orders were given that none of her friends were to be admitted to see her, and she was put under the care of one special nurse during the day. Did not sleep, except in snatches, for the first three nights. There was great wasting of the muscles of the extremities, and altogether the girl appeared very helpless.

On Sept. 22nd, three days after admission, "massage" was ordered, with the "special massage diet." For the first twenty-four hours massage seemed to have but little effect, and she did not sleep after it. It was performed morning and evening, for twenty minutes each time.—24th: She slept for one hour after massage. No screaming fits and no involuntary passage of urine.—26th: Slept well at night, going off soon after the massage was finished. Required to be fed with a spoon, and was a considerable time over her meals.

On October 7th the patient had been steadily improving; took her food well; seemed more sensible; could feed herself; had not spoken at all yet. A week later she was very much better, could sit up and feed herself. Had spoken to the nurse and addressed her by name.—21st: She was able to talk and all choreic movements were absent. Thenceforth she got up and went about the ward and could do everything for herself.—26th: She was quite well enough to be discharged, but in the evening her temperature rose to 104°, she complained of sore-throat, and in the morning she was covered with the scarlatinal rash. She was removed to the Fever ward, had slight albuminuria, and at the end of six weeks was discharged quite well. There was still a slight systolic whiff at the apex.

Remarks.—It was noted that on October 23rd she was quite well—that is to say, thirty-four days after admission. May this be said to be due to the "massage," to the rest in bed, or to the isolation from her friends and relations, or to all three combined? She never had any medicine at all for the chorea.

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Cases of so-called Erythema Gangrænosum.—The Pathology of Diphtheritic Paralysis.

The ordinary meeting of this Society was held on Jan. 9th, Professor J. Marshall, F.R.S., President, in the chair. The subject of Dr. Fox's paper on erythema gangrænosum was illustrated by some models from Guy's Hospital Museum; and in addition to the microscopic specimens of the spinal

cord in diphtheritic paralysis, showed by Dr. Kidd, some similar specimens were exhibited by Mr. Horsley.

A paper was read on two cases of so-called Erythema Gangrænosum, by Dr. T. Colcott Fox. The term erythema gangrænosum has been applied to cases in which the inflammatory patches presented very different degrees of severity, and were not all gangrenous. Case 1 was a lady, aged forty-seven, in whom gangrenous patches continued to evolve off and on from June, 1877, until the present time. The patches were limited to the regions of the chest and arms, and occurred over and over again about the site of former patches, sometimes for a time forming only on one arm, then on the other, and then about the chest, but a sort of symmetry was often kept up. The formation of patches was very frequent at first, but as the general health improved and the habit of intemperance was avoided, the patches were seen less frequently. She showed none of the ordinary signs of hysteria, but at one time had an attack of paraplegia lasting two or three months. Case 2 was a girl, aged seventeen, of an extremely hysterical and neurotic temperament, in whom severe inflammatory vesicating areas (not gangrenous) continued to form for many months. They occurred with fair symmetry over the body and extremities, but there was here also a marked tendency for the patches to recur about the sites of former lesions. In neither of these cases was there any cachectic condition sufficient to account for the severity of the lesions, and the surfaces healed fairly well. The question at issue is whether there exists an idiopathic affection consisting in the continued evolution of inflammatory areas of different degrees of intensity and often gangrenous, such as have been described under the term erythema gangrænosum, or whether these cases should not invariably be pronounced to be artificial. In support of the first proposition there are only five cases on record of a similar nature in which malingering has not been actually proved, but these cases are all surrounded by the greatest suspicion, for they occurred in females, generally young, and decidedly hysterical or eccentric. The sites of attack and mode of evolution of the patches was most peculiar; there was an entire absence of any enfeebling condition sufficient to account for the occurrence of gangrene, and at the same time a healthy reparative process went on; and the patches were such as might be produced by a caustic agency. Dr. Fagge's case of gangrenous patches occurring in a man in the last stage of tubercular phthisis, Charcot's acute bedsores, and varicella and vaccinia gangrænosum were examined in support of the possibility. In opposition to the first proposition and support of the second there are a number of cases on all-fours with the others as regards site and mode of evolution of the eruption, the sex and character of the patient, etc., in which malingering has been proved from the simple erythema produced by mustard, and the excoriations brought about by rubbing, to the gangrenous patches caused by the application of nitric or sulphuric acids.—Dr. Thin referred to a discussion which lately took place at the Vienna Society of Medicine, upon a case shown by Dr. Neumann, of spontaneous gangrene of the skin in a young female. He described the change as commencing with discoloration of the epidermis, passing rapidly to the formation of a bulla and then to gangrene, the consequent sores healing very slowly. Neumann, Kaposi, and other dermatologists admitted the reality of the affection, which was disputed by the surgeons present, amongst whom Professor Billroth urged strong reasons against the probability of such a gangrene occurring in a healthy young subject, and main-

tained his opinion that the condition was artificially produced, although chemical analysis failed to detect in the sloughs any traces of acid, etc., likely to have been used for the purpose.—Mr. Savory instanced two cases under his care at present, showing that in certain subjects there is great proclivity to gangrene. One was a man about forty years old, in whom, after a compound fracture of the leg, gangrene occurred not only at the seat of the injury but also over a large surface of the thigh; and the other an older man, admitted into hospital with two areas of sloughing of the skin, each the size of the palm, following a slight contusion. In these and other cases of extensive sloughing after injury, he had generally found there was a history of alcoholic intemperance, and, therefore, it was probable that their tissues were debased and prone to gangrene. Dr. Fox's cases fell into a different category, being in women without such history and without manifest injury. Mr. Savory pointed out that the detection of the artificial use of caustics was facilitated by noting the shape of the patches, which showed greater irregularity in outline, especially of the lower margins (from the gravitation of the fluid) than is the case in patches of true skin disease.—Dr. Buzzard mentioned a case of a young girl with hysterical paraplegia, in whom a hæmorrhagic bulla formed on the foot, which he attributed to defective nutrition. In another case, also of paraplegia in a female, whom he suspected of malingering, a bed sore was discovered on the trochanter, which he had no doubt was artificially produced, for the patient being closely watched, the sore rapidly healed, the paraplegia remaining.—The President inquired whether in his cases Dr. Fox had had the opportunity of examining the condition of the blood or of the urine, as indicative of any constitutional condition underlying the gangrene. He pointed out that the lesion differed from erythema in having no tendency to spread, and in one of the two cases the state of gangrene was not reached.—Dr. Fox, in reply, said that the case mentioned by Dr. Thin was doubtless one of this class. He had raised the question whether there was any constitutional peculiarity that could determine the lesion in these subjects. The simple bullous eruptions occurring in hysterical women belonged, he thought, to a different class. He had not been able to examine the urine, etc., in these two patients; and, although in one of them no gangrene occurred, it was obviously the same kind of case. He thought the term "erythema gangrenosum" should be discarded.

The next paper read was entitled, a Contribution to the Pathology of Diphtheritic Paralysis, by Dr. Percy Kidd, in which facts are brought forward in support of the view that diphtheritic paralysis is founded on a distinct anatomical lesion of the spinal cord. The lesion affects the anterior horns, and consists in alterations in the shape of the motor nerve-cells, and in changes in their cell-protoplasm. The affected cells are, as a rule, more or less globular in shape, and devoid of processes. The changes in the cell-protoplasm are divisible into two groups. In the first, which is more common, the cell substance has become pale and indistinct, and the nucleus is either absent or only faintly visible. In the second the cells are more granular than usual, and often show a well-marked nucleus. In both cases the cell degeneration has an atrophic tendency. In some cases sections from special parts show a numerical atrophy of motor nerve-cells. These changes are not found throughout the spinal cord, but are limited to certain regions. The localization of the nerve lesion corresponds with the distribution of the muscular paralysis during life. There is no distinct affection

of the neuroglia. The changes are purely parenchymatous. A similar degeneration of the motor nerve-cells has now been found in fifteen cases—viz., by Vulpian in two cases, Déjerine in five cases, Dr. Abercrombie in seven cases, and, lastly, by the author in one case, which is the subject of the present paper. The disease may be described as a "polio-myelitis anterior." It is considered highly probable, if not actually proved, that the above lesion is a constant one, and is the immediate cause of the paralysis. Dr. Buzzard said there could be no doubt that in the case described there was the condition of anterior polio-myelitis, but the author had come to too general a conclusion, since in most cases of diphtheritic paralysis there is disorder of sensation to quite as marked a degree as disorder of motion. The lesions described would not account for this, whilst in some cases the electrical reactions showed but little evidence of such marked lesions. He asked whether the nerve trunks had been examined.—Mr. Parker asked in what way these changes differed from those met with in infantile paralysis, the outcome as to recovery in the two affections being so different. If the spinal change were as complete as in infantile paralysis how could recovery from diphtheritic paralysis be explained.—Dr. Semon also considered that to regard diphtheritic paralysis as an anterior polio-myelitis was a narrow view. He instanced a case of bilateral recurrent laryngeal paralysis following an attack of pharyngeal diphtheria—a case shown to him by Dr. Carpenter—as evidence of medullary lesion. He suggested that in such a case the afferent fibres of the vagus had been influenced by the pharyngeal inflammation, and that the centres of the laryngeal nerves had been implicated in a reflex manner. The aphonia had developed some time after the diphtheritic attack, and had persisted for twelve months; and in such a case he should think lesions would be found in the floor of the fourth ventricle. Similar explanations might be given of the occasional involvement of the cardiac nerves following diphtheria; and he thought that the endeavor should be not simply to confirm the statements of previous observers, but to ascertain whether other changes existed than had been hitherto described.—Dr. Douglas Powell said there could be no doubt at all that in Dr. Kidd's case death occurred from involvement of the respiratory muscles in the paralysis due to the spinal cord lesion; and other cases, as those mentioned by Drs. Buzzard and Semon, pointed to central lesions. There are also cases of death from paralysis in diphtheria in which the lesion seems to be peripheral rather than central. He had been struck with the extreme anæmia of the subjects of this disease, who died with symptoms of cardiac paralysis; in one case the red corpuscles were only 14 to 17 per cent. in number, and very marked fatty degeneration of the heart had been found in some cases.—Mr. Horsley understood that Dr. Kidd did not limit the lesions of diphtheritic paralysis to changes in the cells of the anterior cornua; but there was no alteration of sensation in the case he recorded. The specimens he exhibited were forwarded by Dr. Mott, of Liverpool, and showed vascular engorgement of the spinal cord and medulla, atrophy of the inner group of the ganglia cells in the anterior cornua of the lumbar enlargement, with a distinct increase in the substantia gelatinosa in the posterior cornua; the latter change probably causing disorder of sensation. He was unable to give clinical details; but the changes were confirmatory of those described by Dr. Kidd.—Dr. Kidd, in reply, pointed out that there were now fifteen cases of diphtheritic paralysis on record in which these anterior cornual

lesions were present. There was no disorder of sensation in his case. He had been unable to obtain any of the nerve trunks for examination; but Déjerine describes granular fatty changes in the anterior and posterior spinal nerves, and in the nerves going to the affected parts; and similar parenchymatous neuritis in the anterior, but not in the posterior, spinal nerve-roots. The spinal changes were very like those of infantile paralysis; and it is not unlikely that in cases of recovery the lesion is but transient. He admitted the force of the remarks of Drs. Semon and Powell, but had in the present case limited himself to the spinal cord.

Cases of Polypoid Tumour of the Bladder removed by Operation.—Operation for Exploring the Bladder by Perineal Section of the Urethra, and for removing Vesical Tumour, Impacted Calculus, etc.

The ordinary meeting of this Society was held on Jan. 23rd, John Marshall, Esq., F.R.S., President, in the chair. The evening was occupied with the reading by Sir Henry Thompson of two papers, bearing on the operation for exploration of the bladder and removal of tumours from that viscus, and the prolonged discussion that ensued. A large collection of preparations was exhibited from the museums of the Royal College of Surgeons, St. George's Hospital, and University College Hospital, also specimens by Sir H. Thompson, including microscopical preparations by Mr. Boyd and Dr. H. Gibbes. At the close of the meeting Mr. Pearce Gould demonstrated Dr. Bigelow's latest modification of his instrument for litholapaxy.

Sir Henry Thompson read a paper on four cases of Polypoid Tumour of the Bladder removed by Operation. The paper consists of the history of symptoms, the removal by operation, and the results, in four cases of vesical tumour, each of large size, one of them extremely so, and filling the bladder. In three the patients recovered, in the fourth, with the large tumour, the issue was fatal. A carefully made microscopical examination is described, and the report is appended in each case.

Sir Henry Thompson also read a paper on an Operation for Exploring the Bladder by Perineal Section of the Urethra, and for removing Vesical Tumour, Impacted Calculus, etc.; with cases. The author desired to ask the attention of the Society to a new method of investigating obscure diseases of the bladder, which promises to be valuable in certain conditions occasionally met with. Everyone sometimes meets with a case in which the symptoms of vesical disease are severe and obstinate, and although very careful examination has been made, he is unable to arrive at a rational diagnosis. The occurrence is doubtless not a common one; in the great majority of cases carefully made observations demonstrate the nature and seat of the disease. But for the exceptional cases, always important—cases generally marked by frequent or persisting hæmaturia of some standing, manifestly not renal, and without local signs of cancerous tumour—he proposes to take decided action, and to submit, further, that such action should not be unduly postponed. The essential step in the method proposed is to examine the entire internal surface of the bladder with the finger, by which means we can recognize the presence of any tumour, large or small, the existence of encysted calculus, etc. The method of doing this was illustrated, and shown to be a proceeding simple and easy of performance, and at the same time one which involves little if any danger to life. It consists in making a small opening from the raphe of the perineum to the membran-

ous urethra, which is opened on a grooved staff just enough to admit the left index-finger to enter the canal and to be pushed on to the neck of the bladder. Provided the anesthesia of the patient is so complete that the abdominal muscles are perfectly relaxed, every portion of the internal surface of the bladder may be brought consecutively by suprapubic pressure into close contact with the tip of the finger, and any deviation from the natural condition, however slight, may be noted. The operation is an external urethrotomy only, and involves neither the prostate nor the bladder. The application of the proceeding not only to diagnosis but subsequently to treatment, was then discussed. It was shown to offer facility for the removal of tumour, impacted calculus, etc. Seven or eight cases in which the operation had been performed were cited, and several examples of tumour were exhibited which had been removed by the author. These latter were examples of a disease which is inevitably fatal unless removed by operation; the signs and symptoms of their presence were discussed. Great care is necessary in examining the state of the patients before having recourse to operation. The two conditions, the absence of which are so important to be assured of before interfering, are: renal disease and cancer. Hæmaturia from either of these sources of course absolutely contraindicates an operation.—The President, after alluding to the specimens and instruments exhibited, and in proposing a vote of thanks to the author, remarked that the subject opened up points on the diagnosis and nature of vesical tumours, and praised the paper for its clear and practical character.—Mr. Lund (Manchester) bore testimony to the practical value of the paper, treating of a class of cases difficult of diagnosis and treatment, which it could now be decided to deal with by external urethrotomy or median lithotomy in place of the more risky procedure of a lateral lithotomy or cystotomy. By this method Sir H. Thompson had shown that it was as easy to explore the male bladder as the female; and he would imagine that the main difficulty in the digital exploration would be in cases of fat subjects with deep perineums. He had seen cases in which the bladder had been opened for tumours by the lateral incision. Two of them were cases of malignant disease, but the third was one he had seen recently with Mr. Whitehead, of Manchester, who, in a letter which Mr. Lund read, says that he first explored the bladder through an incision of the membranous urethra seven years ago, not deeming it a novel proceeding, and that within the past year he had performed the same operation six times; in four of the cases finding and removing growths from the bladder. In all of the cases the chief symptom was alarming and uncontrollable hæmaturia. The case seen with Mr. Lund was that of a medical man seventy years of age, who had suffered from persistent hæmorrhage for seven years, with frequent expulsion of villous shreds. The growth was scraped away with Volkmann's spoon, and the patient has resumed his practice without any further symptoms. In the second case there was much relief from pain and hæmorrhage, but death occurred three months after the operation from causes independent of the bladder. The third case was convalescent two months after the operation. The last case was much relieved, but had only been recently operated upon. Mr. Whitehead concludes that the operation is free from risk, that it affords in most cases ample facility for complete digital examination of the bladder; but that in very stout subjects partial exploration could only be effected, and that it was of great benefit even in cases of malignant disease, for it afforded good drainage and physiological rest to the bladder. Mr. Lund

added that in cases where much hæmorrhage followed removal of a tumour, perchloride of iron could be injected, the vesical mucous membrane being very tolerant of strong astringents.

Mr. Reginald Harrison (Liverpool) related a case recently under his care at the Liverpool Infirmary. The man had long suffered from persistent hæmaturia, and on examination the prostate was thought to be enlarged and indurated. He cut down upon the prostate and found a hard fungating mass with a hard base, which he succeeded in enucleating. There was not much after-bleeding, and the hæmaturia has not since returned (now four or five months). Partial incontinence of urine followed, but was met by a "urinary truss"—i. e., an ordinary truss adjusted to the root of the penis. Mr. Paul, who examined the growth microscopically, reported that it was a specimen of scirrhous carcinoma.—Mr. Durham congratulated Sir H. Thompson upon his successful removal of tumours of the male bladder, but as regards the method described in the second paper he failed to see its novelty. He had performed it at least a hundred times in treating bladder disease, and could confirm Sir Henry's statement as to the ease with which the bladder could be explored by it. The operation was well known to Guy's men as Cock's operation, which was intended to afford relief to an inflamed bladder in cases of intractable stricture. In some cases he had found tumours, cancerous in nature, which he had partially removed. But Cock's operation was performed without the staff as a guide; the commencement of the prostatic urethra being determined by the left index finger in the rectum; and the urethra incised through the middle line of the perineum in front of this point. It was the same operation as Sir H. Thompson's with the exception of the use of the staff. In a case supposed to be one of impermeable stricture that he so dealt with, Mr. Durham found the obstruction to be due to an elongated calculus impacted in the prostatic urethra, which he extracted through the wound. Such a case showed that the operation could be done as well without the staff as with it. It was also of the greatest value as a measure of relief in inflammatory or malignant disease of the bladder, affording drainage and a ready means of washing out the viscous. Hardly any risk was entailed by the operation itself, an operation which was as valuable in its way as tracheotomy.—Dr. H. Wotton mentioned a case which occurred in his father's practice many years ago, where a calculus was impacted in the prostatic urethra. In that case great relief was obtained by raising the pelvis above the level of the head, thus keeping the urine from pressing on the neck of the bladder.—Mr. Henry Morris had performed this median operation several times, and pointed out that in the class of cases for which Cock's operation was done, the urethra was so dilated at the point of incision that no harm was done if the median line were deviated from; but no one, he imagined, would prefer to cut down upon the urethra without a guide if one could be passed. During the past two years he had five times practiced this method for exploratory purposes. The first was a case of encysted prostatic calculus, with much hæmorrhage; diagnosis was obscure, and recovery ensued. Two were cases of obstinate cystitis, both with great relief to the symptoms, although one succumbed to renal disease secondary to the cystitis nine weeks after the operation. A fourth case was that of an old man who had suffered from incontinence and constant pain for some time, and was admitted into the hospital in an exhausted state. Mr. Morris forthwith made the incision, and explored the bladder with the finger, removing a large slough. A short

tube was inserted, and, although the patient lived only two days, he was relieved of his pain and slept for several hours, which he had not done for many weeks previously. After death a central sloughing area was found, attributed to contact with the catheter; and at one spot this sloughing had penetrated the serous coat, extravasation being prevented by adhesions. The last case was still in hospital. It was one of enlarged prostate with much hæmorrhage, which required frequent catheterism, and Mr. Morris thought it right to explore through a median incision. Although the patient is thin and tall, he could not reach the neck of the bladder with the finger in the wound, the prostate being so enlarged and lengthened. This illustrated one difficulty which might arise in the digital exploration. The patient is now using a catheter through the wound, but all hæmorrhage has ceased, so it was probable that the source of the blood was from the congested prostate.—Mr. Vincent Jackson (Wolverhampton), pointed out that Sir H. Thompson had not claimed novelty for this method of entering the bladder, but for its application to the diagnosis and removal of tumours, finding no other plan of avail than that which allowed him to explore every portion of the bladder with the finger. He (the speaker) had often tapped the bladder through the perineum in cases of stricture, and well remembered Mr. Quain doing so at University College Hospital twenty years ago. This method of opening the bladder permitted not only of drainage, but of ready irrigation.—Mr. T. Smith assured Sir H. Thompson that it was not a "new" method, for it was one with which he had been familiar from his earliest surgical days. He also thought it was the usual practice to examine the bladder with the finger after lithotomy. It had long been customary at St. Bartholomew's Hospital to examine the bladder with the finger introduced through the incision described, and he appealed to the author, as such operations were often done to remove sources of irritation, to strike out the phrase "a new method."

Mr. Spencer Wells pointed out that the removal of tumours from the female bladder often affords permanent relief. One of his first cases at the Samaritan Hospital was that of a woman, who was bleeding to death from a small mucous polypus, which he extracted, with the result of complete restoration to health. He had since twice removed similar polypi with the same good result; so that he thought some of these cases supposed to be malignant were really innocent growths.—Mr. Berkeley Hill thought it interesting that all the growths removed by Sir H. Thompson were fibromata, which were said hitherto to be rare forms of tumour of the bladder. For his own part he would prefer using the wire écraseur to the forceps in removing large senile growths, for fear lest important structures might also be torn away. Billroth has in such cases removed the tumour by a compound operation, opening the bladder from above. There is no difficulty in exploring the bladder provided it be empty.—Mr. Morris explained that in his case the bladder was completely empty; its neck could not be reached owing to the great length of the prostate.—Dr. Aveling suggested that the female bladder might be opened for the removal of large growths through the vesico-vaginal septum, the urethra not allowing of much scope.—Mr. Eve said that histologists were gradually coming to admit that all these growths of the bladder were fibrocellular in nature, ordinarily described as papillomata. There are, however, forms of papillomata, "villous tumours," which pass into epitheliomata, with scattered growths elsewhere in the mucous membrane, and liable to recurrence on

removal.—Mr. Stanley Boyd said that two of the tumours he examined for Sir H. Thompson were quite smooth on the surface, and only presented minute villous projections. They were mainly composed of fibrous tissue, like that which forms the central part of a villous tumour. All tumours on mucous surfaces tend to become papillomatous.

Mr. Durham explained that his point was that the urethra could be opened in the perineum satisfactorily and well in cases where a staff could not be used.—Mr. Shattock thought more regard should be paid to the pathology of these tumours, and suggested that in malignant cases portions of the bladder should be excised on the same principle as excision of the pylorus was practiced for cancer of that region. The bladder had been successfully sutured after rupture. He exhibited an instrument, constructed in the form of a lithotrite but with blades which worked laterally, as useful for detecting tumours, and removing them if small. He also pointed out that papillomata were generally seated at the trigone—i.e., near the three orifices of the bladder, and they might be compared to warty growths occurring at other outlets; moreover, the mucous membrane at the trigone was less movable than elsewhere.—Sir Henry Thompson, in reply, said that although he had endeavored to make his paper clear he was forced to declare that he had been misunderstood. The operation, which at Guy's Hospital was associated with the name of Cock, had been known for two centuries; it was practiced particularly by the French surgeons, by whom it was known as "la boutonnière." It was not a cystotomy nor a median lithotomy. The conditions for which Mr. Durham operated were in cases of stricture, etc., and for these cases the operation was a well-recognized one. Its present novelty consisted in its extension to cases for which it had never yet been thought of, cases in which there was no means of detecting organic disease save by digital exploration. Out of fifteen cases in which he had performed the operation for diagnostic purposes he had discovered tumours in five cases; and he asked if either at Guy's Hospital or St. Bartholomew's, five cases of tumour so detected and removed during life had been dealt with. There were no specimens of such cases in their museums. They were cases usually overlooked, treated in the medical wards by styptic injections, and he believed that his suggestions would result in finding many such cases. Mr. Smith's remark, that it was always the custom to explore the bladder with the finger after lithotomy, was so far true because the finger is already in the bladder; but how often is a digital examination made for a second stone. As a rule, the sound is introduced for this purpose because the whole interior of the bladder cannot be explored, as it can be by the median urethral incision. He was glad to hear Mr. Whitehead's experience, and believed that these tumours were more common than was suspected. In one of his cases, seen with Sir W. Jenner, where there had been persistent hæmaturia almost to death, he had removed a scale of phosphatic matter, and the hæmorrhage had not recurred. He doubted Mr. Harrison's case being one of scirrhus; it seemed rather one of those fibroid growths of the prostate which can be enucleated.

—A short time ago the librarian of the Faculty of Physicians and Surgeons of Glasgow made an interesting "find" in a dusty corner of the library, having come across a set of manuscript notes of John Hunter's lectures on Surgery, taken by a pupil.

PATHOLOGICAL SOCIETY OF LONDON.

Cirrhosis of Liver.—Cancer of Oesophagus.—Lympho-Sarcoma.—Larynx from a Case of Tubercle.—Ulcerative Endocarditis.—Heart Disease.—Fibrinous Concretion on Pleura.—Lardaceous Disease of Liver.—Vesical Polypus.—Rickets in a Baboon.

THE annual meeting of the above Society was held on January 2nd, Dr. S. Wilks, President, in the chair. For the first hour the ordinary business of the Society was transacted, and during this time the ballot box was open and in the charge of Dr. Edmunds and Mr. Eva, scrutineers. The last half hour was devoted to the special business of the annual meeting.

Dr. Angel Money showed a specimen of Cirrhosis of Liver from a child, aged eight, who suffered from ascites for ten days before death. She had stayed at a beer-shop for two months when three years old, and on her return home it was found that she had acquired a taste for alcohol. There was no history of syphilis. The liver weighed 19 oz. The amount of fibrous overgrowth was very excessive. There was no fibroid overgrowth elsewhere. The history justified the belief that the cause of the disease was alcohol.—Dr. Wilks said there had been two or three similar specimens shown recently from quite young children in whom there was a history of drink, although in many others there was no such history.

Dr. Norman Moore exhibited four specimens:—1. Carcinoma of Oesophagus, a carcinoma affecting the whole middle part of the Oesophagus. The new growth infiltrated the whole wall, and had caused a stricture just admitting a large probe. The oesophagus was adherent to the lung, and at the adhesion its wall was perforated, so that any food which passed the stricture might enter the lung. The lung at this point was not gangrenous, but was simply pneumonic. The distribution of the secondary masses of new growth was interesting. The stomach was not affected, but the small intestine had several firm, whitish constricting masses, of precisely the same relations to the tube as that in the oesophagus. There were numerous secondary growths in both lungs, and one in the outer wall of the left ventricle. The liver, spleen, mesenteric glands, and both kidneys contained numerous masses of the same. The growth was a scirrhous carcinoma, and the secondary masses were all of firm texture. The patient was a man aged fifty-six. He had symptoms of dysphagia in May, and died in December. Out of twelve cases of carcinoma of the oesophagus examined at St. Bartholomew's since 1867 all were males. In six the lower end was the seat of the growth, and in five the middle of the oesophagus. In four cases secondary growths were found in the lungs. Exhaustion was the commonest cause of death. Ulceration into a vessel occurred in two cases, gangrene of the lung in one, and fatal pleurisy in three. The ages of the patients were from thirty-six to fifty-eight.—2. Lympho-sarcoma invading the Duodenum. The growth originating in the lumbar glands had penetrated the duodenal wall and produced at one place narrowing and elsewhere dilatation of the duodenum. The specimen was from a woman, aged forty-one who died in St. Bartholomew's Hospital, under the care of Dr. Gee. During life an irregular ovoid tumour was felt in the epigastric region. The greater part of the tumour was dull on percussion. A lesser region was resonant. The dull part proved to be where there was the greatest infiltration with narrowing of the intestine; the resonance was not due to in-

testine in front of the tumour, but to the dilated duodenum. The patient's illness was of about eight months' duration. The first symptom she noticed was a pulsation in the abdomen. After a time attacks of vomiting came on, which usually began a quarter of an hour after taking food. The lumbar and mesenteric glands and the duodenum were the only parts infiltrated.—3. Endocarditis with Miliary Abscesses of the Heart in a case of Hip-joint Disease. The hip-joint showed denudation of the cartilage on the acetabulum and head of the femur, and was full of pus when opened, as also was the right sterno-clavicular joint. The heart showed growths on and destruction of the aortic valves, and an ulcer on the upper part of the ventricular wall. The walls of both ventricles showed numerous minute specks looking like tubercles, and there were similar specks on the pericardium near the apex, and also in the liver and mucous membrane of the small intestine. On the surface of the brain there were similar specks surrounded by injected patches. The spleen and kidneys contained softened infarcts, and so did the right lung. There was a slight degree of pericarditis, a considerable right pleurisy, and some peritonitis. The little specks were found on microscopic examination not to be tubercles. They had no reticulum and no giant cells, and yielded no bacilli. They were merely collections of leucocytes, and were, in fact, very early abscesses. The patient was a boy, aged sixteen. He had a fall on November 11th, 1882, and a few days after acute inflammation of the joint, though not well marked externally, seems to have begun. Endocarditis followed. Two days before his death he became suddenly hemiplegic, and showed some symptoms of tubercular meningitis.—4. Chronic Inflammation of the Glottis, from a woman aged twenty-five, who died with phthisis under the care of Dr. Church in St. Bartholomew's Hospital. During life she had dysphonia, dysphagia, and dyspnoea. She had been recently confined, and the duration of her phthisis was unknown. The dyspnoea suddenly became urgent, and she died before tracheotomy could be performed. The vocal cords, arytenoid cartilages, aryteno-epiglottidean folds, and epiglottis were all greatly thickened, and by their thickening occluded the glottis. At the root of the epiglottis there was a small erosion, and all down the trachea there was a long patch of redness and ulceration. No tubercle was visible in the larynx or in the trachea. There were cavities in both lungs.—Dr. Goodhart said that last year he brought forward evidence of the occurrence of ulcerative endocarditis in groups. He had himself seen two or three cases lately, and he would like to know whether others had met with cases recently.—Dr. Curnow said that there had been three cases at the Seamen's Hospital in the last three months.—Dr. Wilks asked whether the infarctions were secondary to the endocarditis, which itself was secondary.—Dr. Curnow said that in the three cases he had mentioned the ulcerative disease was secondary to old valvular disease.—Mr. Walsam asked Dr. Norman Moore if any examination was made of the laryngeal muscles in the case, as lately there had been very peculiar changes described in the muscles, tubercles between the muscular fibres and some change in the fibres themselves.—Dr. Norman Moore replied that he had not been able to satisfy himself that ulcerative endocarditis had not been epidemic at St. Bartholomew's. He examined the specks in the endo and pericardium and liver for bacilli (Ehrlich's method), and satisfied himself that there was none. There was no tubercular disease of the larynx itself; there was only great thickening.

Dr. Turner showed a Heart with stenosis of the mitral opening, calcareous thickening of the mitral curtains, and a cluster of recent vegetations along their line of contact and upon the adjacent part of the wall of the auricle, and also upon the aortic valves. Both auricles were dilated, and the left much thickened. A sacculated fibrinous coagulum about the size and shape of a hen's egg was found lying loose in the left auricle; its surface was in places smooth, in others roughened, and it appeared to have been formed some time before death. Its contents had escaped through a large rupture at one end. It appeared to have been at one time continuous with a clot still adherent to the left auricular appendix. A very similar specimen had been already shown by Dr. W. Ogle. The heart was obtained from the body of a woman, aged thirty-four, who died soon after her admission to the London Hospital. She had had an attack of acute rheumatism two or three years before. During life a double bruit was heard over the apex and a doubtful diastolic bruit down the left side of the sternum. A smaller loose fibrinous coagulum, the size of an almond, was found in the right auricle. The lodgment of the large loose coagulum, above the mitral orifice, must have embarrassed the action of the overtaxed auricle. The discharge of the contents of such a large clot must also have had a profound effect. The case was also interesting in that recent vegetations were found upon the tricuspid valve concurrently with those on the left side of the heart.—Dr. Turner also showed a portion of the base of one lung, near the edge of which was attached by a narrow pedicle a branched body half an inch in diameter, like a piece of coral, white with a smooth surface, firm and elastic. It was concentrically laminated, without appearance of organization, and resembled the melon-seed bodies of synovial membranes and the rounded concretions sometimes found in serous membranes. The specimen was obtained from a man aged seventy who died from cystitis and pyelo-nephritis; he also had bronchitis and emphysema. There were loose fibrous pleuritic adhesions of old date, but not near this body.—Dr. Turner further showed the Liver of a man aged thirty-four who died from pneumonia; he had had syphilis ten years previously. The liver weighed eleven pounds three ounces, was uniformly enlarged, firm, and smooth; it stained with iodine in a manner typical of lardaceous disease, and there was a lobulated appearance of the liver suggesting cirrhosis in addition. Microscopically examined it was found that this appearance was produced by areas of liver tissue surrounded by a zone of tissue highly infiltrated with lardaceous material, in which only an incomplete network of liver cells was recognizable. The lardaceous degeneration appeared to be seated in the capillary network, and by the swelling up of that network to lead to the compression and atrophy of the liver cells. This was seen both in the tissue intermediate between the apparently healthy liver tissue and the infiltrated areas, and also in certain small lardaceous deposits scattered through the islands of liver tissue. The kidneys were lardaceous. Heart hypertrophied. Grey hepatisation of the upper lobe of one lung with purulent pleurisy, and old fibroid thickenings at the apex of each lung.—Dr. Barlow asked whether these appearances were not due to changed gummata. He had seen a liver which was stained very deeply with iodine in places, while the liver substance around was healthy, and he considered these were retrograde gummata; the patient was syphilitic.—Dr. Norman Moore had seen two such livers; parts of them were normal, while in parts the amyloid reaction was obtained; there was no history of

syphilis in these cases.—Dr. Turner said that he was not of opinion that these deposits were gummata; for in all of these infiltrated areas there were signs of liver cells, and the change was fairly uniform throughout the whole organ.—Dr. Goodhart thought it a very difficult question to decide. Specimens in Guy's museum which had been believed to be retrograde gummata had been very carefully examined by Dr. Fagge a year or two ago, who concluded that they were really examples of lardaceous disease.—Dr. Curnow asked Mr. Barlow if in his case the gummata were as numerous as the infiltrated patches in the liver shown by Dr. Turner.—Dr. Barlow said the liver was very much enlarged, and he did not suspect the existence of gummata until he applied the iodine test. There was no sharp line of demarcation between gummata, syphilitic infiltration, and cicatricial contraction.

Mr. Shattock showed a specimen of Polypus in the Bladder of a female child, aged one year and a half. The tumour was in structure exactly like a nasal polypus, and it was evidently capable of removal; part of it occupied the urethra; both ureters were dilated; kidneys healthy.

Mr. Sutton showed the Skeleton of a Baboon (West African), aged a year and a half, with Rickets. The liver was lardaceous; the other viscera healthy. The bones were very vascular, and their curves much exaggerated. The epiphyses all showed the characteristic changes of rickets, the line of ossification being very irregular and enclosing islets of cartilage. The calvaria was thickened, but a condition not unlike cranio-tabes existed below the superior curved line of the occipital bone; the occipito-mastoid suture was still unclosed. The right radius articulated on the inner aspect of the right ulna, and rested on the coronoid process of the ulna, and both of these bones articulated with the trochlea of the humerus. This, he thought, was due to detachment of the lower epiphysis of the humerus at a very early life. Monkeys cut their milk teeth very early, and so these escaped the disease. In this baboon the dental follicles of the permanent teeth were enormously thickened, and he thought this might account for the delayed dentition in rickets. In the rickety epiphyses the lime salts are deposited irregularly, so as to circumscribe small islands of cartilage, and he suggested the name of diffuse epiphysis for this condition.—Mr. Eve thought that in animals we had the purest form of rickets; the bones were very different from those in children; they were very porotic; skulls and long bones as well, particularly in lions, and with this but a slight degree of curvature. There is only a slight irregularity of the epiphysial line, far less than in children. He thought that in man the islets of cartilage occurred in the end of the diaphysis rather than in the epiphysis.—Mr. Clement Lucas asked as to the time of development of this baboon, and as to the diet and habits of this animal. He had observed rickets in a greyhound, which strayed from home, and only returned after some weeks with severe and advanced rickets, and recovered under proper diet.—Dr. Goodhart remarked on the lardaceous liver, and asked whether monkeys were above suspicion in the matter of syphilis.—Dr. Barlow said that the rickety liver in children did not stain with iodine as this was said to do.—Mr. Sutton said monkeys at the Zoological Society's Gardens lived about ten years. He found cartilage islets in both diaphysis and epiphysis, and particularly when there were two or three centres of ossification, as in the humerus. This baboon was fed on nuts, fruit, soaked bread, and the gifts of the visitors. He hoped soon to show the skeleton of a rickety lizard.—Dr. Wilks said there was a skeleton, said to be that of a syphilitic monkey,

at the Anthropological Society.—Mr. Sutton had never seen any evidence of syphilis in a monkey.

The following card specimens were shown:—Ruptured Stomach from a child aged four years, by Mr. John R. Lunn; Renal Calculus and Abscess (Traumatic?), Rupture into Left Pleural Cavity, by Mr. John R. Lunn; Deposit of Lime Salts in Mucous Membrane of Hepatic Ducts in an Ox, by Dr. B. G. Morison.

Bromide Rash.—Epithelioma of Bladder.—Syphilitic Disease of the Cerebral Arteries.—Syphilitic Inflammation of the Capsule of the Liver.—Keloid after Scraping for Lupus.

The ordinary meeting of this Society was held on Jan. 16th, J. W. Hulke, Esq., F.R.S., President, in the chair. There was a long list of specimens, but, as a prolonged and animated discussion took place upon a case of presumed Syphilitic Disease of the Liver, shown by Dr. Sharkey, a large number were held over to the next meeting.

Mr. Hulke, the newly elected President, addressed the Fellows as follows:—"Gentlemen—On taking for the first time the Presidential chair to which your votes have lately elected me, allow me to return you my very warm thanks, and to tell you how much I am touched by this mark of your confidence and appreciation. I feel it to be a distinction so far beyond the desert of any work I may have accomplished in connection with our Society, that I cannot put aside the idea that I must in some measure owe it to the friendships it was my happiness to make during the many years I was in office as councillor, secretary, and treasurer. On the threshold of my occupancy I must ask your indulgence for an omission—I refer to the inaugural address, as given, I am informed, by my two immediate predecessors in office. It is only a very few days since I first learned this to me new practice, and the interval has been too short for me to prepare anything in the guise of an address worthy of your attention. I shall, however, cherish the hope of endeavoring to atone for the present omission at the close of my tenure of office."

The report of the Morbid Growths Committee upon Mr. Kesteven's specimen of Hamatoma of the Spinal Canal was read by Mr. Godlee. The report described the characters of the tumour which had invaded the spinal column, and which was found to be of a sarcomatous nature. An interesting feature was the discovery of masses of micrococci in the growth, suggestive of some septic infective process towards the close of life. The report was signed by Messrs. Beck and Godlee.

Dr. Horrocks showed a case of Bromide Rash in an epileptic girl, thirteen years of age, who for the past three months had been taking the bromide of potassium in fifteen-grain doses three times a day. The rash appeared on the leg four weeks after the commencement of treatment. There was no history of congenital syphilis.

Mr. Berridge exhibited a specimen of Epithelioma of the Bladder. The patient had suffered from attacks of hæmaturia for upwards of two years before his death, which occurred rather unexpectedly, the man being at work as a porter within a week of the event. A ragged ulcerated surface two inches in diameter was found in the bladder, and there was inflammation of the right kidney. Dr. Mansell Moullin had made a microscopical examination, and pronounced the disease to be a villous epithelioma.—The President observed that the case was of clinical rather than pathological interest, and remarked upon the difficulty of diagnosing the extent of disease in such

cases, and the impracticability of operative interference in a case like the present.

Mr. Berridge also showed as card specimens a specimen of Cartilaginous Aortic Valves from a man who died suddenly; and a Foreign Body (a "coin-catcher") extracted from the oesophagus.

Dr. Sharkey showed microscopical specimens of Syphilitic Disease of the Cerebral Arteries, from a man, thirty-six years old, who first came under Mr. Nettleship's care at St. Thomas's Hospital with commencing retinitis, and a syphilitic eruption, three months after contracting syphilis. Three weeks later there was commencing iritis, and it was thought that cyclitis would supervene. He complained of pain in the head, but ceased attendance for some weeks, when he returned to the hospital with the eye well, and with pain in the right side of the head. The ophthalmoscope showed no changes in the eye, and he was transferred to Dr. Payne's care. A few days later he was attacked with convulsions, and became semi-comatose. He was admitted into the hospital, and was found to be hemiplegic on the right side, and to be mentally enfeebled. The left pupil was smaller than the right. There was no loss of sensibility. There was much albuminuria. He became increasingly comatose, the temperature rising to 107° before death, which occurred eight days after admission, being preceded by an attack of general convulsions. At the post-mortem examination the arms and trunk were observed to be covered with a copper-colored rash; the lungs contained small hæmorrhages, and the kidneys were slightly granular. The dura mater was thick and adherent, but there was no meningitis. The left middle cerebral artery was partially blocked by a firm white thrombus, and there was softening of the outer part of the lenticular nucleus on this side, but not of the cortex cerebri. The right middle cerebral artery was completely plugged by recent thrombus, and there was extensive softening of the hemisphere, as well as of the lenticular nucleus. The ventricles were distended with fluid. The affected arteries showed on microscopical examination two distinct kinds of change—viz., a chronic fibroid thickening of the subendothelial connective tissue of the intima, and a recent round cell infiltration of the adventitia. This latter change varied in extent in different parts of the vessel, in places penetrating the muscular coat and separating its fibres. In the right artery the change was limited to the outer coat, but the left in which the thrombus was organizing presented extension of the process in the middle coat, as well as masses which might be regarded as gummata. Arterial disease is usually regarded as a late event in syphilis, but in this case only seven months had elapsed since infection. The symmetrical involvement of the vessels was also of interest in connection with this early occurrence. The external coat of the vessel was here the starting point of the change, and not the inner coat as usual.

Mr. Godlee mentioned the case of a gentleman who, at the age of sixty, contracted syphilis, symptoms of nervous disease appearing within seven months of the primary attack. The order of his symptoms was as follows: pain in the head, then severe iritis, then cutaneous eruption, and while this was present he was attacked with hemiplegia and aphasia followed by mental derangement, for which he is now in an asylum.—Mr. Kesteven inquired as to the results of ophthalmoscopic examination in Dr. Sharkey's case.—Dr. Ormerod had lately published in *Brain* the record of a case where, in addition to endarteritis of the cerebral vessels, as described by Heubner, there

were masses of small round-celled infiltration in the external coat. This change had produced no obvious narrowing of the vessel, nor thrombosis, nor cerebral softening, but may have so interfered with the circulation, by the loss of arterial elasticity, as to starve the brain and produce the symptoms of prolonged somnolence and stupor that were exhibited.—The President instanced the case of a young footman, twenty-two years of age, admitted into the Middlesex Hospital, under his care, with left hemiplegia and diplopia, having contracted syphilis about seven or eight months previously. He was transferred to Dr. Cayley's care, and died shortly afterwards. In that case there was extensive syphilitic disease of the cerebral arteries.—Dr. Sharkey, in reply, said that there were no changes in the fundus of the eye, ophthalmoscopic examinations being regularly made. He had not been able to establish any connection between the change in the adventitia and that in the intima. He expressed his belief that such early involvement of the vessels in syphilis was not very rare.

Dr. Sharkey also exhibited a specimen of Syphilitic Inflammation of the Capsule of the Liver. The patient, a man fifty-five years old, came under Dr. Murchison's care at St. Thomas's Hospital in 1876 with diarrhoea, and mottling of the abdomen. There was a history of gonorrhoea, but none of syphilis. The liver was greatly enlarged, extending to the umbilicus, and a tumour could be felt in connection with it between that spot and the xiphoid cartilage. There was no pain, no ascites; and Dr. Murchison suggested that the case was one of a rare form of cirrhosis limited to the left lobe of the liver. Two years later he was admitted under the care of Dr. Bristowe, having been well in the interval to within three days of his admission, when he had a severe attack of hæmatemesis. The abdomen was now distended; there was slight jaundice, and the liver reached to the umbilicus. There were also a few small retinal hæmorrhages. He died two weeks after admission from a recurrence of the hæmatemesis. At the post-mortem examination ascites was found, the spleen was firm, and the liver was much diseased; it weighed 6 lbs. 7 oz.; its surface was coarsely nodulated, its outline distorted. The capsule was greatly thickened, and there extended from the capsule into the substance of the organ, to the depth of an inch or more, an ingrowth of tough fibrous material, which microscopically presented a fibro-cellular and reticulated structure, the deepest parts being the most richly cellular. Numerous small caseating gummata were contained in this new growth, which penetrated into the hepatic lobules, the liver cells themselves showing hardly any alteration. The cirrhotic tissue was very vascular, and some of the hepatic vessels were amyloid. In some parts the bile-ducts were increased in number. Dr. Sharkey considered the changes to be very different from those of alcoholic cirrhosis, and that the presence of gummata decided its syphilitic origin, although there was a marked history of drink and none of syphilis. The process was diffused over the whole surface of the organ, and had extended in a remarkable way into its substance.—Dr. Mahomed inquired if there were any other signs of syphilis, and thought the use of the term "gummata" in the description of the case was misleading. Small yellow patches occur in ordinary alcoholic cirrhosis, and the drawing shown by Dr. Sharkey was consistent with these being ordinary inflammatory material. He hoped to show a specimen of a liver he had recently met with, in which a portion of the greatly shrunken right lobe was almost completely severed by a strand of fibrous tissue from the rest of the

organ. The left lobe was greatly enlarged, presenting the characters of alcoholic cirrhosis, and there was no evidence of syphilis in the body. Had the left lobe shown the same appearance as the right such a liver would have been called syphilitic; but he maintained that in all such cases there ought to be collateral evidence of syphilis before arriving at this conclusion.—Mr. Butlin thought it was rather a strong assumption to regard the appearance of these small gummata near the surface of the liver as conclusive of syphilis, and was surprised that no other signs of syphilis had been met with. He suggested that the specimen should be referred to the Morbid Growths Committee.

Dr. Green said that from his experience he would regard the naked-eye characters of gummata to be so characteristic that there could be no possibility of a mistake in the diagnosis. It would be interesting to learn if other members of the Society had seen localized fibroid changes in the capsule of the liver except in syphilis. Syphilitic lesions of the liver were quite familiar and unmistakable.—Dr. Norman Moore suggested that in assigning syphilis as a cause of morbid changes the precise evidence in favor of syphilis should be stated, such as chancre, nodes, cutaneous eruptions, etc. In the absence of such evidence the syphilitic nature of the visceral lesion must remain undetermined. Capsular thickenings may be due to local pressure as well as to cicatrization around gummata. It is generally stated that if the connective tissue dipped deeply into the substance of the liver it was probably syphilitic; but that a mere thickening of the capsule was generally due to local causes. But he had lately seen an instance where a capsular thickening, due to local pressure, had penetrated into the liver substance.—Mr. Roger Williams mentioned two cases he had recently seen; in one the right lobe was completely atrophied and cirrhotic; in the other the same lobe was not only cirrhotic, but was covered by a very thick capsule.—Dr. S. West pointed out that there were only two affections giving rise to small caseating nodules—viz., syphilis and tuberculosis; and in some forms of chronic peritonitis the capsule of the liver becomes very much thickened, the thickening extending some distance into the liver.

Dr. Goodhart protested against the necessity of establishing other signs of syphilis in cases where there are gummata, the characters of which are distinctive, and the presence of which was quite conclusive of syphilis. Had it not often happened that the presence of these definite changes in the liver was quite sufficient to show that the patient had syphilis?—Dr. Coupland believed that the peculiar form of interstitial hepatitis associated with capsular inflammation in syphilis was quite distinctive, even in the absence of gummata or of specific lesions in other organs. He asked whether the testes had been examined in this case; for although the absence of fibroid change in these organs would not negative syphilis, the presence of it would be strong confirmatory evidence.

Dr. Buzzard asked if any ophthalmoscopic examination had been made. The presence of old choroiditis or iritis had repeatedly clinched a diagnosis of syphilis.—The President, in calling upon Dr. Sharkey to reply, suggested that the specimen should be referred to the Morbid Growths Committee.—Dr. Sharkey would be very pleased to have the specimen referred. He said there were no characteristic signs of syphilis elsewhere in the body; but he thought it absurd in the present state of knowledge to deny a syphilitic origin to such changes unless there had been evidence of sec-

ondary manifestations. There was not the slightest doubt as to the growths he had described being gummata. In no case of alcoholic cirrhosis that he had examined had he met with masses of connective tissue that could possibly be confounded with gummata. In this specimen they appeared as small masses of irregular outline, caseous in the centre, with a peripheral cell growth, which does not occur in other cases of caseous degeneration of inflammatory products. As Dr. West had said, such masses could only be syphilitic or tubercular, and a tubercular inflammation of the capsule of the liver lasting for three and a half years was unknown. Although the history was negative as regards a chancre, the patient had had gonorrhoea; and syphilis may be contracted with only this primary manifestation. He had no notes as to the condition of the testes or the penis. The ocular changes were limited to small retinal hæmorrhages.

Dr. Clutton showed a living specimen of Keloid after scraping of lupus of the cheek. The case was peculiarly interesting on account of the development of keloid in other parts of the body—viz., at the seat of incision-wounds in the shoulder and hand for the removal of necrosed bone, whereas in a similar wound in the leg, which had incompletely healed, no keloid occurred. The keloid developed in the cheek six months after the lupus had been scraped away. Mr. Clutton instanced the supervention of keloid in some cases of superficial ulceration of various kinds, as pointing to the probable tendency of certain individuals to develop this disease of scars. In some cases scars which have long been present may develop keloid synchronously with the appearance of keloid in a recently found scar.—Mr. Clement Lucas had seen four or five cases of keloid arising after scraping for lupus. In one case the keloid was quite as unsightly as the lupus itself, but it had since entirely disappeared. Mr. Clutton's case was interesting in the multiple development of keloid, and in the fact that at the wound which continued to suppurate the keloid did not develop. He strongly advised that no attempt should be made to remove keloid, as it invariably recurred.

Mr. Butlin suggested that the strumous condition of the patient might account for the keloid formation. Scars in strumous subjects are prone to become swollen and reddened. He had always regarded keloid as an evidence of constitutional weakness, and in the case mentioned by Mr. Lucas the disappearance of the keloid may have coincided with the patient's improvement in health.

Mr. Marrant Baker asked what form of lupus it was, for in a case where he had thoroughly excised a lupus patch there appeared a very unsightly keloid in the cicatrix. That, however, was a peculiar form of lupus hypertrophicus, and he would think it rare for keloid to occur after operation for lupus vulgaris.—Mr. B. Squire said that keloid was not rare after scraping for lupus, whereas linear scarification was never followed by this unsightly affection.—Mr. Sutton instanced a fact often pointed out by the late Mr. Critchett—viz., that the cicatrix following the operation of peritomy for pannus was at first very large and vascular, but in course of time, as the scar contracted, the vessels diminished in size and number, and the pannus, which at first appeared to be increased by the operation, was cured.—Mr. Clutton, in reply, said the case was one of true keloid, and not simply a thickened scar. It was the ordinary form of lupus.

Dr. S. West showed some specimens of the Bacilli of Tubercle prepared by Ehrlich's method.

CLINICAL SOCIETY OF LONDON.

Symptoms resembling Myxœdema.—Enlargement of the Lower Lip.—Transpatellar Excision of the Knee.

THE annual meeting of this Society was held on Friday, January 12th, Mr. J. Lister, F.R.S., in the chair. The last half hour of the time was devoted to the special business of the annual meeting. The cases described were: one of a child presenting many of the appearances of myxœdema, one of remarkable hypertrophy of the lower lip cured by operation, and one of excision of the knee-joint by an incision carried through the patella.

Dr. Coxwell related the case of a child, aged thirteen, with symptoms resembling those of Myxœdema. Until eight years of age she differed in no way from other children, and could read, write, and learnt arithmetic. A great change then came over her; she would often fall asleep even when eating her meals; her memory became defective, and if sent to do anything she would wander about in an aimless fashion. Later her speech became thick and indistinct, she suffered from headache, her head drooped forward on to her chest, her hands and feet became very cold, her legs became weak and her gait unsteady. She was lately a patient in the National Hospital for the Paralyzed and Epileptic, under the care of Dr. Hughlings Jackson. The appearance of her face is very suggestive of myxœdema, her skin being translucent, with a circumscribed patch of redness in the centre of the cheeks, the lower eyelids swollen, the nose broad, the eyes prominent and heavy looking. Her limbs are slender and well formed. The thyroid gland seems diminished, and there are no abnormal fatty tumours in the region of the neck or elsewhere. While under operation her temperature was frequently as low as 95°6". She was often extremely restless at night, and had frequent attacks of screaming. Her power of speech became worse, till at last she could hardly utter a single sound, the lips being seen to move ineffectually while she attempted to do so. She could not kiss her mother or puff out her cheeks, and her food would often remain seven or eight minutes between her teeth and lips. There was a general over-clouding of the intellect. Dr. Coxwell drew attention to the fact that very pronounced mental disease has been reported in myxœdema, and that Dr. Ord has had a patient suffering from that disease with marked affection of the bulb, a point of similarity with the present case of some importance. If the case was one of myxœdema, it was of interest as being the first recorded in a child. If it was one of simple imbecility, it was remarkable on account of the bulbous symptoms and the likeness it bore to myxœdema. The arguments in favor of sporadic cretinism were few, and were out-balanced by the absence of most of the characteristics of that disease.

Mr. J. N. C. Davies-Colley read notes of a case of enormous Enlargement of the Lower Lip, cured by operation. Richard B. D—, a clerk, aged thirty-six, was admitted into Guy's Hospital in August, 1881, with a remarkable swelling of the lower lip. Fourteen years before he had a chancre (?) on the penis, followed by soreness of the tongue and swelling of both lips, especially the lower. There was never any rash on the skin. He was a very great drinker. The lower lip was of enormous size, everted and pendent, so that its border was on a level with the tip of the chin, while the lower teeth were in front completely exposed to view. The mucous membrane was fissured in parts, but otherwise natural. The tissues were a little firmer than usual, but not at all indurated. There was a

little tenderness on pressure. From side to side it measured three inches, from above downwards an inch and a quarter, and in thickness seven-eighths of an inch. The upper lip and tongue showed signs of chronic inflammation. There was no enlargement of the adjacent glands. He left off smoking, and was at first treated with anti-syphilitic remedies. The mucous membrane became more healthy, but the lip remained of the same size. Some reduction was then effected by pressure between thin slips of wood. The lip became smaller and flaccid, but was still everted and pendent. On November 8th a V-shaped piece was removed from the centre of the swollen lip, and a rapid recovery ensued. When last seen he had no longer any eversion of the lip, which had assumed a perfectly healthy and normal aspect. Mr. Davies-Colley brought the case forward as a striking example of the enlargement of the lip which occasionally results from chronic inflammation. There was nothing in the patient's family history to indicate a scrofulous tendency. The evidence of secondary syphilis was doubtful, and there was no record of mercurial salivation. On the whole, Mr. Davies-Colley was disposed to attribute the disease primarily to syphilis and secondarily to the irritation of the inflamed surface by excessive smoking. Mr. Clement Lucas had seen this case, the interest of which, he thought, lay rather in its cause than in its cure. He believed that any chronic ulceration of the lip might produce such hypertrophy. He thought that the so-called strumous lip was far oftener due to congenital syphilis than to struma. He suggested that the internal use of mercury might have had some effect upon producing this hypertrophy. He remarked, too, that smoking was very injurious in those suffering pain from secondary syphilis, as it kept up the ulceration of the lips and tongue. He referred to a young lady who suffered from chronic thickening of the upper lip in which there were two lateral incisors which were carious and stopped, and at the bottom of one of them was a sinus. On extracting these two teeth the œdema quickly subsided. He asked whether the teeth in Mr. Colley's case were all sound.—Dr. Hadden thought that this hypertrophy corresponded to a form of lymphatic obstruction which had been described by certain German authors as occurring in the tongue: the microscopic appearances bore out this view. He did not think the evidence pointed to the syphilitic nature of the affection.—Professor Lister thought the case very interesting from its rarity, and also from the success of the treatment, for the part of the lip left behind returned to its normal size, and in this respect it resembled the contraction of an hypertrophied tonsil after excision of its more prominent portion, with at the same time lessening of the thickening of the Eustachian tube and the neighboring parts, and thus improvement of hearing, so often observed after this simple operation. The same thing happened in lipoma of the nose. In a case where he had removed the greater part of a large unsightly mass of chronic inflammatory thickening, the neighboring diseased part of the skin improved and the nose was now almost normal.—Dr. Meadows mentioned the case of a lady with enlarged mons veneris and labium, which he removed with an écraseur. Although only thirty-three years of age, menstruation entirely ceased in two or three months, probably from sympathetic atrophy of the ovaries.—Mr. Davies-Colley remarked that the tension of the parts of the lip left and the correction of the pendulous position of the lip were important in leading to the recovery of the parts not excised. He did not see any evidence of lymphatic obstruction; there were no enlarged

glands. He had no note on the condition of the teeth except that the necks of the exposed teeth were denuded by retraction of the gums, and were thickly covered with tartar. He thought the hypertrophy was due to secondary syphilis and to the continuous irritation of tobacco smoke.

Mr. Golding-Bird read a paper on a case of Transpatellar Excision of the Knee, which he had previously exhibited to the Society. The operation was in the person of a lad, aged thirteen; fairly healthy himself, but with a family history of phthisis. There was a year's history of articular ostitis of the right knee with pulpy disease. Excision was eventually performed on May 9th, 1882. It differed from an ordinary excision in that the transverse incision was made across the middle of the patella, which was then sawn in two, the two fragments, with the soft parts, being turned up and down. The excision was then completed as usual, the articular surfaces of the tibia and femur being removed. Some pulpy thickening was removed from the underside of the patella, and when the limb had been straightened two carbolized silk sutures were passed through its substance, and its two fragments thus united. Primary union was obtained, and nothing more was seen of the patella sutures. Until September 12th he walked about with a stiff bandage at the knee and with crutches; after that date he was ordered to discard all support. He now has a movable patella and half an inch shortening. He has all the advantages of retaining the patella; but besides that, there is a gain by this method of operating, since the surgeon can freely examine and manipulate the joint, more freely, indeed, than where, with the idea of retaining the knee-cap, the lateral incisions are employed. Two great advantages remain to the patient by keeping the normal attachments of the patella: The quadriceps opposes the ham-strings, so that the necessity is obviated of employing a stiff bandage for years to prevent posterior displacement of the leg; the rectus femoris, considered as arising below, has its full play upon the trunk in preserving equilibrium, whilst it also allows of the perfectly natural forward motion of the limbs in walking; this last is not the case where the ligamentum patellæ has been sacrificed.—Mr. Howard Marsh thought all surgeons must be dissatisfied with many of the results of excision of the knee, and he was very glad of this suggestion of Mr. Golding-Bird's, which seemed to be an obvious improvement.—Mr. Gant thought that it was rare to find the patella not involved in the disease when excision of the knee was necessary. When not diseased he had left the patella, and he had not seen any advantage from so doing. His results after removal of the patella had been very good. In the average of his cases of excision the union took place in three months, and he then put on a movable back splint for a further three months or less. In one case, a woman aged fifty-three, the patient was up within two months and a half.—Mr. C. Heath said Mr. Golding-Bird's case was a very successful one; but he agreed with Mr. Gant that in most of the cases usually submitted to excision the patella was diseased; in fact, when the patella was free an argument against excision was found. He thought that Mr. Golding-Bird's case was in an early stage of disease, and might possibly have been treated by other means. He thought, too, that even where the epiphysal cartilage was not, to all appearance, interfered with, the operation was attended with impaired growth of the limb.—Mr. Lister said that many years ago Volkmann advocated the transpatella excision of the knee. If he thought only of the old-fashioned excision of the knee in cases with open sinuses, and without strict asepsis,

he should quite agree with Mr. Gant. But if the skin were unbroken, he would proceed on totally different principles; he would remove a much smaller part of the femur, have a broader surface for union with the tibia, and cause less shortening. In such a case none of the patella need be taken off, and possibly the lagging behind of the growth of the limb might be prevented by leaving the action of the quadriceps unaffected. He was, however, doubtful whether excision of the knee was really needed, in Mr. Golding-Bird's case. In many similar cases in this practice free antiseptic incision, with scraping away of the diseased synovial membrane and gouging out of diseased bone, had preserved limbs of normal length, and even movable at the knee-joint.—Mr. Golding-Bird, in reply, said that the case was one which might have succeeded under such treatment as Mr. Lister had described. At the time of the operation there was some lateral movement with grating in the joint, and the ligaments and fibro-cartilages were replaced by pulpy tissue. If the case had been in private he should not have operated, but his experience with hospital out-patients was that if left alone they ended unfavorably. He thought that, in young people especially, when the patella was removed there was a tendency to posterior displacement of the tibia, to guard against which it was necessary to wear some form of apparatus for months or even years.

The business of the general meeting was at this period proceeded with, and subsequently the meeting adjourned.

EPIDEMIOLOGICAL SOCIETY.

At the meeting on December 6th, 1882, Dr. Edward Seaton, Medical Officer of Health and Physician to the General Hospital, Nottingham, read a paper on the Influence of Small-pox Hospitals. The author commenced by giving a description, illustrated by photographs, plans, and maps, of the hospital accommodation at Nottingham. It was centrally situated and divided by a wooden fence, only six feet high, from public thoroughfares. It was difficult to carry out the principle of isolation thoroughly for the following reasons:—(1) There was no suitable provision for a resident medical officer; (2) communication over the wooden fence, already mentioned, between those inside and those outside the hospital could not be prevented; and (3) some of the medical men who had conveyed private patients to the hospital, and whom they still continued to attend, were not very careful to adopt all requisite and practicable precautions. A new hospital was, however, to be built in a more retired situation. The Poor-law Authority had a kind of joint proprietorship with the Sanitary Authority in the present hospital. Dr. Seaton then gave some instances of people suffering from small-pox refusing to be conveyed to the hospital, and who thus became centres of infection. He next elucidated, by a series of maps he had prepared, the gradual development of the epidemic, different colors being used to indicate cases which were kept at home and badly isolated, cases kept at home and fairly well isolated, and cases removed to the hospital. The cases which were kept at home were, whether well isolated or not, generally followed by other cases in their immediate neighborhood. The exceptions to this rule were due to vaccination, which had an influence controlling the spread of small-pox more powerful than that of isolation. One disadvantage that attended the removal of the worst cases to hospital was that it undoubtedly tended to encour-

age that indifference or repugnance to vaccination which was so sedulously cultivated by anti-vaccinationists, and which arose to a large extent from ignorance on the part of the people as to what small-pox unmodified by vaccination really was. How is it that small-pox spreads more rapidly at one time of the year than at another? How is it that in one epidemic it would assume a much more malignant form than in another? These are points that the science of epidemiology has yet to solve, but with regard to small-pox it may be said that it is practically preventable by vaccination and revaccination. The disease first made its appearance at the Union Workhouse on Nov. 14th, 1881, the case being removed to the hospital at once. Whilst at the workhouse the patient was in the "skin ward" with fourteen others. Of these fourteen seven contracted the disease. There were a few other cases which occurred at the workhouse about this time, and one person died there. But after the commencement of the epidemic the workhouse with its 618 inmates, was free from the disease, in spite of its close proximity to the hospital, and notwithstanding that there had been very little revaccination carried out. A large Board School was situated near the hospital, and of the 410 boys attending it only two were attacked, and in each of these cases there was ample opportunity for the illness to have been contracted in the ordinary way. Primary vaccination would, however, protect the vast majority of those at school age. Several cases had occurred on the east side of the hospital, and as the prevailing wind during the first five months of the epidemic was from the west a supposition had arisen that the infection was carried in the atmosphere from the hospital as a centre. Considerations negating this view, however, were:—(1) The number of cases at a distance of half to three-quarters of a mile from the hospital was greater than the number occurring in the close vicinity of the hospital huts; (2) there was no simultaneous outburst of cases such as might have been expected had the semina of small-pox been widely scattered in a still active state amongst a population which was proved to be susceptible. On the hypothesis of aerial infection, and having regard to the close proximity of the hospital, it was certainly very difficult to account for the immunity of some "hands" working in a factory only about thirty yards from the hospital. Two of these persons only were attacked, and in one of these cases the source of infection may be said to have been traced. It must be remembered that they were employed at all times of the day and in all conditions of the atmosphere. Personal contact was, however, in this case prevented. Had it been permitted it is highly probable that a larger number would have contracted the disease. In conclusion he exhibited a map which showed the localities in which all the fatal cases occurred during the epidemic of 1871-72. At that time there was no registration or notification of cases of sickness, and therefore this map had not the same significance as those previously exhibited. Still, it was a noteworthy fact that the deaths from small-pox during that epidemic (1871-72) were chiefly aggregated in localities far removed from the hospital, the immediate vicinity of which, especially on the north and east sides, was remarkably free. This quite coincided with the facts given by Dr. Thorne Thorne (Report of the Medical Officer, Local Government Board, 1882, p. 210), and statements made by other medical men in the neighborhood, which went to show that, though the hospital was fuller during the former epidemic than it had ever been during the recent one, there was less small-pox in the neighborhood than in other parts of the town.

A meeting of the Epidemiological Society was held on January 3rd, at University College, Dr. George Buchanan, F.R.S., in the chair.

A paper was read on the Planning and Construction of Hospitals for Infectious Diseases, by Mr. Gordon Smith. The author commenced by stating that, having regard to the serious pecuniary loss, no less than to the vast amount of individual anxiety and misery, caused by outbreaks of epidemic disease in any district, it is surprising that the degree to which it is possible to prevent the ravages of such outbreaks is at present so imperfectly appreciated by the public. Hospitals for infectious disease must provide for the admission and treatment of at least two kinds of infection, the arrangements being such as to allow of this being done with reasonable security that a patient admitted for one disease shall not contract another disease consequent on his stay in the hospital; for small-pox the accommodation ought to be so completely separate as possible. Indeed, where practicable, it is well to have an entirely separate hospital for that disease. The site for a hospital must be of such extent as to allow the several buildings to be at an ample distance from the boundaries, and well separated from each other, so as to permit free circulation of air about, and access of sunlight to, them, and at the same time prevent inter-communication among the nurses and patients occupying the several ward-blocks. Spare land should also be kept to provide for future extensions, permanent or temporary, and also as a recreation ground for convalescent patients. The extent of site should be such as to allow not more than twenty patients to the acre, and the land should be effectually enclosed with a solid fence not less than six feet high. The hospital buildings may be divided into three classes—viz., (1) the administrative; (2) the patients' department; and (3) the various out-offices. The administrative department should stand in advance of the ward-blocks and be moderately near the entrance gates, in order to prevent tradesmen and others coming into contact with the nurses or patients. Patients must be rigorously excluded from this department, and it must be easily accessible from the buildings set apart for the treatment of patients. It should contain the usual domestic offices, store rooms, and apartments for the care-taker and medical officer. In the upper story ought to be situated the nurses' bedrooms, and a bath-room is a useful adjunct. The patients' department must be so arranged as to have distinct open-air communication between every ward-block and the administrative department. Between each pair of wards in each ward-block it is advisable to have the nurse's room, bathing accommodation, and a small but well-ventilated pantry in which the supply of milk, beef-tea, etc., for the day or night's use may be kept. It is inadvisable to exceed twenty beds in a single ward-block in a hospital for infectious disease. Wards of two or more stories in height are objectionable as increasing the difficulty of supervision and administration, and the vitiated and infected air of the lower wards will be likely to find its way into the upper wards. A few small wards for one or two patients each are always useful in an infectious hospital. Plans prepared by Mr. Keith D. Young, architect, were then exhibited, showing an arrangement of private rooms at a hospital for infectious diseases which Dr. Charles West hopes to get built at Nice. Windows with double-hung sashes and floors of oak or red deal, polished with beeswax and turpentine, are generally preferred for wards. No cornices, mouldings, etc., on which dust can lodge are permissible, and it is recommended that all internal angles should

be rounded. Waterclosets and sinks, which should be placed in a projection from the end of each ward, should be separated from the ward by a cross-ventilated lobby, the closets themselves also having means of cross-ventilation independent of the lobby. For warming, stoves and hot-water pipes are recommended; and for the admission of fresh air, openings having an area of about 100 square inches are recommended in the opposite external walls at the floor level, one behind each bed. The wards should be elevated by means of arches slightly above the level of the ground, and the ground underneath, and for a short distance around the ward, should be covered with a layer of concrete. The out-offices comprise washhouse, disinfecting-house, ambulance and dead-house. The washhouse and laundry should be large; the disinfecting chamber should be near the laundry, and have a thoroughly efficient apparatus capable of dealing with mattresses, bedding, etc., as well as ordinary clothing and carpets. The drainage of a hospital for infectious diseases differs in no essential point from that of any other building. The drains should be laid in direct lines, with uniform gradient between the points where a change of direction or of gradient occurs, and at each of these points means of access to the drain should be provided either by a lamp-hole or a man-hole, so that the entire system of drains could be inspected with ease at any moment.

The above paper was followed by an account of the use of Tents for the Treatment of Small-pox, by Mr. G. W. Collins, who has had experience of this mode of treating small-pox during the summer of 1881 at Finchley, and at Wednesbury during the recent epidemic in that district. He claimed the superiority of the hospital marquees over the Redcliffe tent and wooden buildings, on the following grounds: 1, the marquee contains double the amount of cubic space; 2, the ventilation can be regulated at will; 3, a more even temperature can be maintained with less trouble. During the summer of 1881, when in charge of the small-pox hospital at Finchley, he found that with a temperature of about 104° in the sun the tents could be kept perfectly sweet by looping up the sides and opening both ends. In neither epidemic did the tent-life give rise to any pulmonary complications.

In the discussion which followed the reading of the two papers, Dr. Thorne, Surgeon-General Gordon, Dr. C. E. Saunders, Dr. Collie and Messrs. Saxon Snell and Robins took part.

MEDICAL SOCIETY OF LONDON.

A Case of Anæsthesia and Analgesia.—Tension of the Abdomen and its Variation.

A MEETING of this Society was held on Dec. 15th, 1882, Mr. F. Mason, President, in the chair.

Dr. de Havilland Hall read notes of a case of Anæsthesia and Analgesia. The patient, a boy twelve and a half years of age, had suffered "on and off" with headache since a fall upon the chin three years before; and two weeks before admission he is said to have temporarily lost power in the right hand and arm. He occasionally fell down, and five days before admission had a fit in the night. He, however, appeared quite well when seen, and complained only of some pain and tenderness in the right thigh and loss of feeling in the thumb. At times he saw everything "red." Examination proved the thumb to be perfectly anæsthetic and analgesic—a condition which obtained to a certain degree over the whole body.

(23)

On Dec. 5th he complained of headache; on the 6th of pain in the lower part of the legs; and on the 7th there was found perfect anæsthesia and analgesia in both legs, from the soles of the feet to an inch and a half above the patella. He could walk well, but said he could not feel the ground under him. The special senses are normal beyond slight deafness in right ear, attributable to a chronic otorrhœa, and impairment of the smell in right nostril and of taste in the right half of the tongue. There was no history of diphtheria. His father had epilepsy. The case was brought forward on account of the sudden appearance of anæsthesia in the legs, which may disappear as suddenly. The boy suffered much from worms.—Dr. Owen suggested that the cause of the complaint might be in the digestive tract.—Dr. Wiltshire alluded to a case in which pain in one arm, with hyperæsthesia, followed by ascending paralysis of the limb, followed a blow on the thumb. The patient, a young lady, rapidly recovered under mercurial friction. He also mentioned a similar case produced by a fall on the hand; and a case of sciatica relieved by like treatment after morphia had failed. The morbid condition ascended in these cases from the injured extremity towards the cord. Dr. Heron thought the exaggerated tendon reflex pointed to some cerebral lesion, and suggested that the case was one of contrecoup.

Dr. Braxton Hicks read a paper on the Tension of the Abdomen and its Variations. First of all alluding to the form of the abdominal cavity, and its natural tendency to assume the spheroidal shape, unless interfered with by its bony wall, the author discussed the physical conditions of the viscera within, or implanted, or attached to its walls. He then described the tension normally existing both between and during respiration, pointing out work he had already done and published in the Royal Society's Proceedings, and that the respiratory movement of the abdomen could be registered as a wavy line on the drum of an instrument, like the cardiograph. He then demonstrated that the effects of body and limb movements were very powerful on this wavy line, and that tension was not only increased thereby, but also lessened to a similar degree, and that thus the belief of many obstetricians that at times there was an insuck into the cavity, received confirmation. This being accepted, the author then pointed out the conclusions which followed, of much importance practically—namely, that any opening existing, it was possible by any sudden movement for any irritating or septic matter to be drawn into that opening, whether it ends in a lymph space, veins, or peritoneum, and as pressure was momentarily taken off from the vena cava and iliac veins, a rush from the veins below would occur, which might detach and move heartward any clot in the femoral vein. Dr. Hicks then showed the effects of increased tension on the organs and on the muscular system, both of the abdomen and general body, and the effects of the opposite state, showing that without external support the abdominal vessels unduly filled, robbing the general system of so much of its blood, causing the shrivelled, flabby, and worn-out appearance of those who had lost along with the flaccidity of their abdominal walls the tone of the vascular system, and that the abdominal vessels being full of blood, a facility for hæmorrhage from uterus or bowel, etc., is given. The effect of relaxed peritoneum, as bearing on positions of the liver, uterus, etc., was then noticed, as also the effects of the pressure from within on the pregnant uterus. The paper ended with allusions to many other points flowing from the consideration of the subject

OBSTETRICAL SOCIETY OF LONDON.

A MEETING of this Society was held on January 10th, 1883, Dr. Matthews Duncan, President, in the chair.

Sacral Teratome.—Dr. Heywood Smith exhibited a Fœtus of about five months' intra-uterine age, having an outgrowth from the end of the coccyx about three inches and a half long, and seven inches in circumference. This consisted mainly of embryonic tissue: small round cells with a faint fibrillar arrangement. From the coccyx were traceable four vertebrae, consisting each of a cartilaginous body with spinous processes.

Porro's Operation.—Dr. Heywood Smith also exhibited a Uterus removed by Porro's operation. The patient was a primipara aged twenty, the conjugate diameter of whose pelvis was one inch and three-quarters or less. She had been in labour two days, and attempts at delivery by craniotomy and cephalotripsy had been made without success. The performance of Porro's operation occupied nearly an hour. The specimen showed clearly the rugæ on its peritoneal surface.

Superfetation (?)—Dr. Outthwaite exhibited a body looking like an Ovum of about a months' intra uterine age, which had been passed within thirty-six hours after the birth of a full-time child. The specimen was referred to a committee for examination and report.

Notes of a Specimen of Antelexion of the Uterus.—A paper by Mr. W. S. A. Griffith on the above subject was read. The specimen was one in the Museum of the Sussex County Hospital at Brighton. The uterus was sharply antelexed, and was fixed, and the adjacent parts agglutinated into one mass by firm old adhesions. The uterine cavity was dilated into a sac the size of an almond, and contained the remains of a clot. The patient had died from peritonitis while menstruating. Except for a previous attack of peritonitis, she had had remarkably good health. She was unmarried, and had never complained of painful menstruation until asked, during her fatal illness, when she said she had pain towards the ends of her periods. The bend was at the junction of the body and cervix. The cervical canal was not contracted, but rather larger than usual. There was no atrophy of the uterine wall. The author rejected obstruction as a cause of the dilatation, which he thought due to chronic congestion. He thought the specimen interesting as showing that acute flexion of the uterus might exist without interfering with the nutrition of the uterus, or with the general health.—Dr. Routh thought this specimen did not prove that the canal of a flexed uterus was not constricted; for the patient was menstruating, and the canal became dilated during menstruation. Further, the uterine cavity was here ulcerated, and this might have enlarged the canal.—Dr. Graily Hewitt said that without contraction of the canal there might be virtual obstruction from the coaptation of its opposite walls, and from the swollen congested condition of the uterine tissues resulting from the flexion. This was proved by clinical facts.—Dr. Herman agreed with Mr. Griffith that this case showed no evidence that the dilatation was due to obstruction. There was no angulation nor narrowing of the canal, which was bent in a curve. The uterus was fixed; and if it were admitted that here the dilatation was due to obstruction from flexion it did not follow that the same effect would be produced in a uterus which was free to move.—Mr. Griffith said that microscopic examination showed that the apparent ulceration was due to the patient having just ceased menstruating.

Case of Extirpation of the Uterus and Appendages for Epithelioma of the Cavity.—This paper, by Mr. Knowsley Thornton, was then read. The author thought that these operations being still on their trial, it was a duty to fully report every case. This duty was not sufficiently recognized. This reticence indicated that they were rarely immediately successful, and when they were, gave but a short interval without recurrence. He argued that speedy recurrence was to be expected. He had refused to operate in many cases, and thought that the only justifiable ones were those in which the disease was confined to the cavity or body of the uterus. He then gave at length the history of such a case, with details of the operation, and after progress to death on the fifth day. He referred to the statistics of the operation by the abdominal and vaginal methods. In any future case he would choose the vaginal method, and would avoid the use of ligatures altogether, leaving pressure forceps on for the first few days. These would serve as drains, and at the same time by their weight tend to draw together the wounded surfaces.—Dr. Edis suggested that in the abdominal operation septic infection might be avoided by removing the uterus per vaginam.—Dr. Aveling said that drainage was, he believed, first advised by Purmann in 1706, and in England by Johnson in 1769.—The President had taken part in three of these operations, all of which proved fatal. He was struck with the greater facility of the vaginal operation.—Mr. Thornton replied.

Transfusion.—A paper on this subject by Mr. C. E. Jennings was read. The author remarked on the dangers and difficulty of transfusion, which he thought too grave to be undertaken by a practitioner alone, at a moment's notice. De-fibrination of the blood rendered its nutritive value very small. But the value of transfusion depended primarily not on its nutritive, but on its dynamic, effect. This latter could be procured with greater certainty by the intra-venous injection of a large quantity of saline fluid. He had invented, and elsewhere described, a syphon for such injection. This instrument he had now modified, so that blood transfusion might be combined with the saline injection. The flow of saline fluid into the recipient's vein having been established with the syphon, the blood-donor's vein was opened with a trocar and cannula specially devised for the purpose, and the blood conducted by a tube into one limb of a Y-shaped glass tube, through the other limb of which the saline solution flowed, and by this the blood was carried on into the recipient's vein. Coagulation was prevented by the addition of a few drops of liquor ammoniac to the saline solution. Should the blood-donor become faint, by turning a stop-cock the current could be reversed, and the saline solution made to flow into the donor's vein.—Dr. Aveling thought the interest of the paper was in the proposal to substitute saline fluid for blood. He thought the apparatus a bad one; there was no certainty that blood would flow through it, no way of telling whether it was flowing or of measuring its quantity. The reversal of the current he thought dangerous, tending to carry clots into the donor's circulation. Life might sometimes be saved by auto-transfusion, raising the patient's feet high above her head.—Dr. Routh said that Mr. Jennings's solution contained potash salts. It had been found by experiment that the injection of potash salts was poisonous. The valves in the donor's veins would prevent the proposed reversal of the current.—Dr. Graily Hewitt thought the chief point in the paper was the attention directed to the dynamic effect of transfusion. This, he thought, was probably very important. There was

great difficulty in deciding when the operation was necessary. Patients after post-partum hæmorrhage might rally, and yet perish some hours later without further loss of blood.—Mr. Fenton-Jones thought Mr. Jennings's syphon an admirable instrument. The solution had been used with success, and therefore was not poisonous. He thought the current of saline fluid would act as a *vis a fronte*, and carry on the blood.—Dr. Fancourt Barnes said that he had found it difficult to get the blood to flow from the donor's arm, even with Roussell's instrument.—The president regarded transfusion as little more than a hopeful proceeding, demanding encouragement and study. Patients who survived it were often spoken of as having been saved by it—a manifest mistake. In many cases it had caused death. Sets of cases of transfusion, occurring in single practices within a limited time, were often published; he could not admit that extreme danger occurred so often. Injections of plain water had been used in cholera with splendid but temporary benefit; he would like to see it have a fair trial in cases of hæmorrhage. The attempt to use blood introduced most of the difficulties and dangers of the operation, and these were increased by complicated apparatus. He would use any good, clean syringe, preferably a glass one.—Mr. Jennings only advocated blood transfusion for the minority; he thought it dangerous. He had found by experiment that a few drops of liquor ammoniæ would prevent coagulation. He thought that the collateral circulation through venous anastomoses would allow the saline fluid, when the current was reversed, to enter the donor's vascular system. The amount of blood taken should depend upon the effect of its loss on the giver, not on measurement by ounces.—Dr. Herman said that saline intra-venous injection had been used at the London Hospital in four cases of puerperal hæmorrhage, of which two recovered and two died; water once, and the patient recovered.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

Growth of the Crystalline Lens.—Paralysis of the Third Nerve, with Cerebral Symptoms.—Paralysis of the Sixth Nerve, with Choreiform Movements of the Face.—Movements of the Eyes in Ear Disease.—Peculiar Growth Developing from a Cilium to the Anterior Chamber.

THE ordinary meeting of this Society was held on Jan. 11th, Mr. W. Bowman, F.R.S., President, in the chair.

Mr. Priestley Smith read a paper upon the Growth of the Crystalline Lens, commencing by a quotation from the chapter by Otto Becker, in the Handbook of Graefe and Saemisch, to indicate the present position of knowledge on this subject. He then proceeded to describe an original research carried out during the last two years. He had examined 142 lenses, removed in their capsules shortly after death, from the eyes of eighty-three adult subjects. Special precautions were taken to avoid changes from absorption or evaporation of moisture. Each lens was accurately weighed, its volume was then measured by means of a specially-devised instrument, acting by displacement of fluid along a graduated tube (instrument exhibited); finally, it was measured as to its transverse diameter. The author's aim had been to examine at least twenty transparent lenses in each decade of adult life; this had been accomplished up to the age of seventy; but between seventy and

ninety the numbers were not yet fully made up. Detailed tables were appended to the paper, and the general results were demonstrated to the meeting by charts and diagrams. He had found that the average weight of the lens continually increased, the increase being, roughly speaking, at the rate of 1.5 milligrammes each year. The volume of the lens also continually increased, and in about the same proportion, the increase being at about the rate of 1.5 cubic millimetres each year. By calculation from the weights and volumes it was found that the specific gravity remained, on the average, about the same throughout life, though there were lenses of low and of high specific gravity in each decade. Reservation he considered necessary in accepting linear measurements of the lens after its removal from the eye; but from the data obtained, it was demonstrated mathematically that the enlargement of the lens was not by any means limited to the transverse diameter. The continuous growth of the lens sufficed to explain the acquired hypermetropia of old age without assuming that the lens changed its form; it was also, in the author's opinion, the cause of the shallow anterior chamber of the senile eye, which had hitherto been attributed to an advance of the whole lens, a supposition which could not be reconciled with the acquirement of hypermetropia. The continuous enlargement of the lens, though hitherto unobserved, and though apparently separating this organ from every other in the body, was readily intelligible from a physiological point of view, for the lens is, by development, a cuticular structure, the cells of which, unlike those of the cuticle, multiply within a closed capsule, and cannot be thrown off as they grow old, the older cells being surrounded by the younger. In the tabulated results, the relation of senility to the development of cataract came out clearly. Lenses which showed any opacity were distinguished from the others, and were found, when tabulated, to be, on the average, smaller than transparent lenses of the same age. As this difference was present even when the opacities were very slight, it seemed likely that a period of diminished rate of growth preceded the formation of the opacities of senile cataract. The opacities were in most cases limited to the equatorial zone, where the capsule and cortical layers of the lens were subjected to the traction of the suspensory ligament. This supported the conclusions recently published by Becker concerning the formation of opacity by separation of the fibre layers at the equator, and the bearing of the continuous enlargement of the lens upon certain other morbid conditions.—The President congratulated the Society upon having a paper read before it, which would prove to be a standard paper to which all would refer, and said that their best thanks were due to the author for his labors.—Mr. Higgins asked whether the author's research had led him to an explanation of the reason why presbyopia diminishes in very old people, and why cataractous subjects become hypermetropic.—The President pointed out that from the increase of the size of the lens with age the capsule would become stretched out, and it would be interesting to know if the capsule at the age of seventy is thicker than in early life, or whether it is any way modified as to elasticity by this necessary extension. That again might influence the shape of the lens. He trusted that Dr. Smith would continue his research.—Dr. P. Smith, in reply, could offer no explanation why old people became less presbyopic. There is increased hardness from diminished elasticity, and increased tension of the ciliary muscle, so that there were many factors producing change in the shape of the lens, changes which it was very difficult to record.

The increase in size of the lens must be in antero-posterior diameter, as well as in the lateral, but he could not say whether the increase was uniform in all directions. He had limited himself to establishing the physiological and anatomical facts, before venturing on the pathological side of the question.

Dr. Lees read notes of a case of Paralysis of the Third Nerve, with Cerebral Symptoms, and showed the patient, a girl aged six years and a half, who had been brought to the Hospital for Sick Children on November 10th, 1881, on account of a squint of the right eye and shaking of the left arm and leg. The squint had been noticed by the mother three months earlier, and the shaking began a fortnight after the squint. She had had three fits when a year and a half old, but none since, and had had slight headache over the right eye for a fortnight before she was brought to the hospital. There was complete paralysis of the third cranial nerve on the right side. The pupil was dilated, and did not respond either to light or in accommodation. The upper lid drooped lightly, but no affection of the fifth or seventh nerves could be discovered. Both optic discs were normal. The movements of the left upper limb consisted in slight forward and backward movements of the whole limb in a vertical plane, together with short flexions and extensions of the wrist. They were rhythmical and uniform, and occurred when the limb was not used; and the mother stated that they did not quite cease during sleep, but that they were worse when the child was excited. There was no distinct paralysis of the limb. Similar, but less decided, movements affected the lower limb. No history of congenital syphilis could be obtained, but an infant brother of the patient was subsequently found to be suffering from snuffles, and to have had some rash on the buttocks. After treatment for twelve months with iodide of potassium the shaking of the limbs could no longer be detected, and the squint had entirely disappeared, leaving only a little weakness of the internal rectus. The right pupil, however, remained dilated and motionless; it measured six millimetres, while the left measured 2.5 millimetres. The power of accommodation was entirely lost in the affected eye, and the pupil was still absolutely motionless. Vision with that eye was very imperfect, but by using convex lens of six dioptries she could read small type. Her condition remained unaltered up to the time she was shown to the Society. The case, Dr. Lees thought, presented the group of symptoms to which Mr. Hutchinson had given the name of ophthalmoplegia interna, and which he attributed to disease of the lenticular ganglion, but this case seemed to support the theory that the symptoms were due to a cerebral lesion, probably near the nucleus of the third nerve below the aqueduct of Sylvius.

Mr. Brudenell Carter asked whether any attempt was made to effect contraction of the pupil or change of accommodation by eserine.—Dr. Hughlings Jackson asked whether the patient had headache or optic neuritis, for the symptoms pointed to some affection of the crus cerebri. On the other hand, he never remembered to have seen rhythmical movements in a case of organic disease. Most cases of rhythmical movement of one side were either due to malingering or hysteria.—Dr. S. Mackenzie asked whether the ocular defect occurred at the same time as the affection of the left arm. If there were any interval of time between the two, there was possibly more than one lesion.—Mr. Hutchinson said the case was hardly one of ophthalmoplegia externa, which is motor paralysis of the third nerve, and in the case of ophthalmoplegia interna there is no dilatation of the pupil;

it is rather of small size, and there is never any evidence of action of the fibres supplied by the sympathetic. He thought the child's physiognomy very suggestive of syphilis.—Dr. Buzzard suggested, as the movements of the left arm came on about fourteen days after the paralysis of the right eye, that there may have been some slight loss of power in the left side, to which the irregular movements were sequential. That would imply a central lesion; but on examining the child he found there was no tendon reflex at the left wrist as he would have expected if there were a coarse lesion like a gumma in the crus cerebri. The case, therefore, tended rather to support Mr. Hutchinson's view that the ophthalmoplegia was due to lesion of the lenticular ganglia, and not to central disease; the limb affection being accidental.—Dr. Lees, replying to Mr. Carter's question, said that eserine was not used.—Mr. Carter said he had asked that question because in some cases of paralysis non-recovery was due to atrophy of the muscles, and it occurred to him that by the use of eserine the nutrition of the muscles might be improved, as in other cases it is by the use of electricity.—Dr. Lees had intended to adopt the course suggested by Mr. Carter, but had deferred so doing until he had shown the case. The history was that three months before the child was brought the eye-symptoms had shown themselves. There was no optic neuritis, and there had been a little headache. Although the pupils were dilated they were motionless, and there was loss of accommodation, the main signs of ophthalmoplegia interna, which in this case apparently depended on a cerebral lesion. Improvement had taken place in the eye symptoms and arm symptoms at the same rate. He had seen a case of tumour of the right crus cerebri where there was paralysis of the right third nerve, and of the left limbs. It seemed to him that a gumma of the inner nucleus of the third nerve would explain the paralysis, and that the limb affection might be due to collateral pressure.

Dr. Lees also read notes of a case of Paralysis of the sixth Nerve, with Choreiform Movements of the Face. It was that of a boy, aged eleven and a half years, who had had convergent strabismus from the age of three years. On examination in December, 1882, it was found that the left eye could not be brought to the outer side of the median position; there was no other interference with ocular movements; pupillary reaction and the optic discs were healthy, but each presented a crescent. Spasmodic contractions of the facial muscles, chiefly on the right side, occurred at irregular intervals. Those choreiform movements, as well as headache, which he had suffered from for some months, were probably due to the hypermetropia and astigmatism with which both eyes were affected. There was no paralysis of the seventh nerve.

Dr. Hughlings Jackson read a paper upon Movements of the Eyes provoked by Pressure on a Diseased Ear, and related the details of a case which, he said, resembled one reported by Schwalbach, and was important as giving a demonstration that ear disease was one cause of, or one factor in, producing vertigo. It was a clinical illustration of one of Cyon's experiments on the semicircular canals of rabbits. The patient was a woman, aged forty-nine, who had suffered from otorrhoea on the right side from childhood. She had recently become subject to attacks of auditory vertigo, and had a peculiar unsteady gait resembling that produced by alcoholic intoxication. Pressing on the tragus of the right ear caused certain definite movements of both eyes. First the eyes moved slowly, to the left, then they move back again by jerks to the

right, at the same time she felt giddy and there was apparent displacement of objects to the left. This displacement was synchronous with the slow movement of the left. This patient was examined by Dr. Laidlaw Purves and by Mr. Couper, and under treatment by syringing the ear, and the internal administration of quinine, she improved so that only the very slightest movements of the eyes were producible by the pressure spoken of. Dr. Jackson referred to certain researches by Dr. James, of Boston, U.S.A., which seemed to show that deaf mutes were not easily made giddy by rotatory movements, and were not at all liable to seasickness. In conclusion he thought that the procedure mentioned in this case might probably be helpful in the diagnosis of some difficult cases, and that the different results obtained at different periods, in such cases would be some measure of the patient's progress. In reply to the President, Dr. Jackson said that the slow movement of the eyes was from right to left, and that apparent movement was to the same side, and according to the patient's statement, coincident in time. He referred to a note on this subject by Professor Donders, which he had communicated to the Society last session.

Dr. Maddox contributed a paper descriptive of a New Method of Testing the ordinary relation between Convergence and Accommodation, and exhibited an instrument designed by himself for this purpose.

A paper dealing with a case of a Peculiar Growth developing from a Cilium in the Anterior Chamber, contributed by Mr. Rockliffe (Hull), was read by Mr. Nettleship. The patient was a man, aged twenty-three. In August, 1881, he received a vertical lacerated wound in the outer third of the cornea, and the lower lid was injured at the same time. Six weeks after the accident an eyelash could be seen in the anterior chamber, reaching from the angle of the chamber to the middle of the pupil; there was a slight pink zone round the cornea, and cataract. An attempt to remove the eyelash at this time failed. In Sept., 1882, the eye became acutely inflamed, and, at the inner end of the cilium, was a peculiarly white woolly growth. This growth rapidly increased, and, on Oct. 18th, Mr. Rockliffe opened the anterior chamber, when the tumour, with cilia firmly adherent to it, was carried out with the gush of aqueous. Dr. Brailey examined the mass and reported that it consisted of flattened epithelium cells exactly like the more superficial cells of the conjunctiva; it seemed possible that the cells of the root-sheath had proliferated within the anterior chamber.—Mr. Nettleship some years ago had examined a similar specimen from a patient of Mr. Couper's.—Mr. Power had seen a similar case under Mr. Hancock's care. A boy when climbing cut his eyelid with a lamp he held in his hand, and an eyelash was thus transplanted on to the iris. After a time a new growth started from this and formed a circular mass of hairs, passing round the anterior chamber. The mass was removed without difficulty.—Mr. Couper remembered the case mentioned by Mr. Nettleship. In the chamber it looked like a syphilitic gumma, but on removal Mr. Nettleship found it to consist of epithelium cells together with much cholesterine, so that it was surmised that some sebaceous cells had been introduced with the hair. In this case the hair had curled up in the anterior chamber so as not to be visible until this was opened and the tumour removed.

— ARRANGEMENTS have been made for the meeting of the Sanitary Institute of Great Britain to take place at Glasgow in the autumn of the present year.

MEDICAL OFFICERS OF HEALTH SOCIETY.

A MEETING of this Society was held on Dec. 15th, 1882, Dr. J. W. Tripe, President, in the chair, when a short paper was read by Mr. S. R. Lovett on the Illegal Occupation of Cellar Dwellings. A woman who was nearly dead from cold and hunger had been discovered in a cellar in Dudley-street. The cellar was a small rubbish hole, measuring 13 ft. by 9 ft. The woman had no right to be there; she did not lodge in the house; she was a tramp and a trespasser. A similar case had occurred two years before, when a woman was found dead in a cellar. Such cases occur through the front doors of tenemented houses being left open day and night. People walk in uninvited, sleep in the cellars and on the stairs, use the closets, and even ask for soap and water in the morning. They do not take possession of their sleeping places until night; and, as the Legislature has fixed the hours of inspection of dwelling-houses between 9 a.m. and 6 p.m., the sanitary inspectors are powerless to deal with them. Mr. Lovett, in conclusion, asked what remedy could be found to prevent such illegal occupation. In the discussion which followed, in which the President, Dr. Bristowe, and Dr. Bate took part, the opinion was expressed that the medical officer of health could take no action.

Dr. G. A. Heron then read a paper on the Tubercle Bacillus, of which the following is an abstract. Last June the author began to give attention to the clinical aspect of Koch's discovery of the bacillus of tubercle; sixty-two patients had come under his observation in whose sputa he had detected the bacillus. They were of both sexes, from ten to sixty-five years of age, of various occupations, and all unmistakably suffering from phthisis. In three of these patients he had at first searched the sputa for the bacillus unsuccessfully, but found it in two cases in the third week, and in the other in the seventh week. His experience of the sixty-two cases inclined him to the belief that the presence of these organisms in the sputum would sufficiently indicate the prognosis. Given a persistence for some weeks of fewness of the bacilli of tubercle in the sputum, that case will probably run a long course; on the other hand, given the persistence of a large number of bacilli early in the history of a case, that case will run a short course and end in death. In the cases most rapidly fatal, the bacilli were grouped in numerous masses. Grouping may occur when the bacilli are few as well as when they are numerous, but the feature alluded to is that where the masses of bacilli are numerous they give a characteristic appearance in almost every microscope field. Three or four bacilli in a field indicate the presence of few of these organisms, thirty or more in a field must be regarded as numerous. Koch's work was undertaken in the interest of the public health. He found the sputum when dried, as it may sometimes be seen drying upon a hospital floor, to be as surely fatal in its results when inoculated as when he inoculated with the bacillus obtained by cultivation of the organism from tuberculous tissue. Taking his views as true, we must admit that the expectoration of a consumptive person probably always contains a poison of a most virulent kind. After referring to the deposit of tuberculous sputum upon handkerchiefs and other linen, the author suggested that this might be a possible, if infrequent, source of infection; but Koch has indicated other possible sources of infection, for he has demonstrated the presence of tubercle in animals with which man comes in frequent contact. The question, How does phthisis

spread among mankind? is one of the most difficult to answer, but the explanation must be sought for in the light which Koch has shed upon it by his brilliant discovery.—In the discussion which followed the President, Dr. Bristowe, Dr. Corfield, and Dr. Samuel West took part. Some interesting microscopical specimens of tubercle bacilli were exhibited by Drs. Heron and Samuel West.

A meeting of this Society was held on January 19th, 1883, Dr. J. W. Tripe, President, in the chair.

A paper on an extensive Outbreak of Diarrhoea from polluted water was read by the President, of which the following is an abstract:—On November 6th, 1882, he received information that the inhabitants of almost every house on Clapton Common had been seized with diarrhoea and sickness, accompanied in some cases by more or less depression. Inquiry showed that the milk came from several sources. The chief outbreak occurred on November 4th and 5th. On the 7th, at the request of the author, the Clapton main was thoroughly scoured out. On the 8th fresh cases occurred; and on the 10th the main was again cleansed. Cases also occurred on the top of Stamford-hill, while those at Clapton were likewise confined to the higher part. An examination of the plans of the Company's mains showed that a cross main extended from Clapton to Stamford-hill and adjoining roads, and was connected with the Kingsland and Stamford-hill main at a point immediately below where the disease had occurred, and that the main at Clapton Common terminated in a dead end without any valve. Some hundreds of persons were affected, often several cases occurring in one household. A house-to-house visitation was not made, but the author heard of several cases in which water-drinkers alone in a family were affected, and there were several striking instances in which visitors were attacked. Thus two ladies took luncheon at a house on the common, one drank sherry and the other sherry-main-water; the former escaped, the latter suffered. Another visitor to another house took luncheon and drank water, with the result of being attacked on his return to Chiselhurst. There were three servants in one family, two of whom were water drinkers, the last not; the water-drinkers alone were affected. The disease was not fatal to anyone. Analysis of the water showed but a very slight increase of organic matter; but on November 7th, Mr. Wigner, to whom a sample had been submitted, found some vegetable debris, consisting of fibres, mycelium, and some animalcules, but no sewage fungus. On the 9th there were no animalcules or mycelium. The author believed that the presence of a main with a dead end at the top of the hill had allowed a growth of mycelium, and perhaps of other organic bodies, owing to the water remaining there unchanged for some time, and that they became suddenly mixed with the ordinary supply a day or so before the outbreak. In the discussion which followed, Dr. Corner, Dr. Corfield, Dr. Gwynn, Mr. Shirley Murphy, Dr. Heron, and Dr. James Stevenson took part, and the President replied.

MIDLAND MEDICAL SOCIETY.

The ordinary meeting of this Society was held in the Birmingham Medical Institute, December 6th, Dr. Malins, President, in the chair.

The President showed the Ovaries and Fallopian Tubes which he had removed from two patients. One was single, aged thirty-eight, and had suffered ovarian pain for thirteen years. Considerable ad-

hesions were found in the pelvis. The second patient was married, aged thirty-nine. The left ovary was soft and friable, and was removed with difficulty. Both cases did well.

Mr. William Thomas exhibited Three Polypi of the Rectum, each about three-quarters of an inch in diameter, all of which had been removed from a child six years of age. Allusion was made to the rarity of multiple polypi of the rectum, this being the only case he had met with or read of. He also showed the heads of two Femora, removed by resection from two cases of morbus coxae, which presented similar features. In both the head of the femur rested firmly on the margin of the acetabulum, and at the point of contact the cartilage was completely gone, so that the cancellous tissue of the head of the femur rubbed against that of the margin of the acetabulum. In each case the head of the femur was grooved by the pressure.

Dr. Sanders showed a Fracture and Dislocation of the Body of the Seventh Cervical Vertebra, the posterior edge of the lower inter-vertebral cartilage pressing upon the cord, but without injuring it. There was also a fracture of the left laminar process of the vertebra, but no hæmorrhage into the cervical canal. The patient lived eight days after the receipt of the injury, and during life there was complete paraplegia of all nerves below the first dorsal.

Mr. F. L. Phillips exhibited a man, aged twenty-five, who had been treated for epilepsy for fourteen years, and was now covered with a rash of thirteen months' duration. There was no history of syphilis. The eruption consisted of papules and tubercles on the face and back of shoulders, arms, and legs. Some of them were as large as a walnut, and tended to suppurate at the apices, forming rupial-looking patches, but were not itchy. This condition was attributed to the prolonged use of the bromides.

Mr. Phillips also showed the Metatarso-phalangeal Joint of a man who had had many attacks of gout. The cartilages and ligaments of the joint were infiltrated with fawn-colored urate of soda. The patient, who was a chrome worker, died rapidly from an attack of acute gouty bronchitis.

Dr. C. Lewis exhibited a specimen consisting of a Suppurative Ovarian Cyst, with a uterine attachment, which had been removed from the body of a girl, aged eighteen. Three days before death, having previously been in fair health, malaise and slight tenderness over the right ovary were complained of. The following day there was a high temperature, and all the signs of traumatic peritonitis. The cyst was the size of a hen's egg, containing between two and three ounces of pus, and was very adherent to all the pelvic viscera. A small rupture was found in the cyst wall. The left ovary was also found to be enlarged, and the Fallopian tube to contain a small pyo-salpinx.

Mr. T. Nelson showed twenty Calculi, which one patient had passed per urethram at different times. The stones varied in size, one being as large as a horse-bean.

Dr. Savage read a paper on "Some of the Diseases of the Fallopian Tubes." He referred especially to hydro and pyo-salpinx. These diseases exist, in the author's opinion, much more frequently than is laid down in the text-books; and that there is such a frequency should not seem so surprising, seeing that both uterine and Fallopian tubes are developed from the same fetal structure, Müller's duct. As causes which could be ascertained, he mentioned gonorrhoea, both recent and latent, the abuse of pessaries, especially intra-uterine ones, and pelvic peritonitis or ovaritis. The first effect of inflammation is to cause obliteration of the uterine and fimbriated ends of the

tubes, thus allowing a collection of the abnormal secretion. The relatively large amount of areolar tissue in the wall of the tube, as compared with that in the uterine wall, accounts for pus being so common in the former. Surgery is able to step in and remove where necessary these tumours, the diagnosis of which must often be presumptive, based on the physical signs and the clinical history. The operation is often a difficult and a tedious one on account of the frequent accompaniment of firm adhesions, and the danger of an escape of the fluid contents in the case of pyosalpinx. If left alone the termination may be:—1st:—Resolution and absorption; this would be very improbable where pus is present, and it would not affect the results of former adhesions. 2nd. Bursting into the rectum or vagina, which would have a curative tendency, or into the peritoneum; this would be certainly fatal unless early surgical interference be adopted. The operation for the removal for diseases such as these is an extension in abdominal surgery which commenced in ovariectomy. In the discussion which followed Mr. Ross Jordan, Dr. Malins, Mr. Chavasse, and Mr. Harmer, took part.

Dr. G. P. Best read a paper "On the Methods of applying the Tests for Albumen." After remarking on the importance of the early diagnosis of granular kidney, and the fact that this could only be settled by the discovery of small quantities of albumen in the urine, he glanced at the more careful methods of examination from time to time suggested; and while arguing that the very suggestion of these more elaborate methods implied certain necessities, he brought forward his idea of utilizing the syringe or suction principle for the purpose of meeting them. First was considered the advantage in point of accuracy of the apposition of urine and nitric acid obtained by the use of the syringe; a point most important in those early cases of granular kidney above alluded to in which the quantity of albumen is small. Secondly, the convenience of the application of this method in house-to-house visiting. In illustration he exhibited a pocket apparatus, arranged for him by Messrs. Salt & Son, which exemplified the general principle as well as the particular application. In this portable case Dr. Best substituted for nitric acid the hydrochloric solution of common salt of Dr. Roberts, which acts equally well, and is better suited for packing.

CAMBRIDGE MEDICAL SOCIETY.

At a meeting of this Society, held on December 1st, 1882, Professor Humphry, M.D., F.R.S., President, in the chair, Mr. Wm. Adams, F.R.C.S., Surgeon to the Great Northern Hospital, read a paper on "Dupuytren's Contraction of the Fingers," which was illustrated by a number of plaster casts showing the condition of some of the hands on which he had operated, before and after the treatment. In 1832 Dupuytren described, from a dissection, the anatomical conditions existing in this form of finger-contraction which we now distinguish from other forms of contraction by his name. He demonstrated the fact that the fingers were drawn down by contraction of the fascia alone, and that the tendons took no share whatever in producing or maintaining the contraction, which he found to be entirely removed after division of the fascia. Dupuytren especially described the digital prolongations of the fascia as passing laterally to the sides of the phalanges. He divided these digital prolongations, and was surprised to find that he could at once straighten the fingers; "the tendons [he observed] were not

implicated in any way, and their sheaths had not been opened." Dupuytren's description has since been confirmed by other observers, more especially by Goyrand of Aix; the late Professor Partridge, who placed a dissected specimen in the Museum of King's College; and, it is believed, the late Mr. Stanley dissected a specimen which exists in the Museum of St. Bartholomew's Hospital. In 1864 a good demonstration of the relation of the fascia to the tendons and their sheaths was accidentally afforded the author. A gentleman who suffered from Dupuytren's contraction of the fourth and fifth fingers met with an accident in attempting to hold a restive horse. The contracted fingers were torn open, and the skin in the palm of the hand torn across the sheaths of the tendon were not injured. The tendons in their sheaths were seen lying at a depth from the surface, running along the concavity of the curve, in proximity with the bones, whilst the fascia had evidently been stretched across like the string of a bow. Mr. Adams turned this accidental occurrence to practical account by altering the method of operating, which had previously been based upon the idea of a deep tendinous contraction, which could only be divided by a deep puncture, and passing the knife from below upwards, as in ordinary tenotomy. He now passed it between the skin and the fascia, and cut from above downwards; and he had also modified the details of the operation, especially directing attention to the digital prolongations of the fascia, as they pass to the sides of the phalanges; and improved the mechanical appliances to be used in the after-treatment. The anatomical demonstrations above referred to, he thought, made it clear to any surgical mind that the only rational and efficient treatment must be the division of the contracted fascial bands, which would certainly not yield to mechanical extension. Mechanical treatment is only applicable to very slight cases, when contraction is only commencing. But should the operation be performed by open-wound, or by the subcutaneous method? Dupuytren in the year 1831 operated by open-wound, making three incisions. Suppuration followed, but the case progressed favorably, and all contraction being removed, the natural movements of the fingers were restored. In 1831 Stromeyer re-introduced, in an improved form, the operation of subcutaneous tenotomy, which had been first devised and performed by Delpech in 1816, but only in one case which was followed by inflammation, so that he never repeated the operation. Subcutaneous surgery, therefore, dates its origin from 1831, and was introduced into England by Dr. Little in 1837. The more recent changes have been in favor of a return to the method of operation by open-wound, and the operation recommended by Prof. Busch, of Bonn, is that which has attracted the most confidence. He (Mr. Adams) apprehended, however, that if the subcutaneous method of operating were carefully performed, its results would be far more perfect than could be obtained by open-wound, and without any of the risks which this method must necessarily entail. The tendency to relapse does not exist in any marked degree, but on the contrary is rare and exceptional. Moreover, it is satisfactory to know that the causes of relapse are within control, and that if relapse should occur, the operation can be repeated with a certainty of success.—Mr. J. H. Hough, upon whom Mr. Adams had operated for this contraction, gave an account of his own case. About twelve years previously, when a boy at school, he observed a small swelling in the palm of the left hand. For some time it gave rise to no annoyance, but when an undergraduate he found that he was obliged to give up rowing on account

of the severe pain in the palm which that exercise induced. When a student in London he showed his hand to the surgeon for whom he was dressing, who at once said that the affection was fascial and not tendinous, and suggested an operation. The operation was incomplete as he was not under the influence of an anæsthetic, and unable to bear extension. A year later a more complete operation was performed, and for a time he did very well; as soon, however, as he left off extension the hand relapsed. About a year ago the inconvenience he suffered in consequence of the contraction made him determine to undergo further treatment, and he accordingly placed himself under the care of Mr. Adams. The hand was now perfectly free; a very slight degree of contraction existed in the ring finger, from contraction of one of the digital prolongations of the fascia, which had taken place since the operation, but which gave no trouble.—In answer to Mr. Hough, Mr. Adams said there could be little doubt of the existence of a gouty tendency in the great majority of cases of this form of contraction.

Mr. Lawrence Humphry (of the Victoria Hospital for Diseases of the Chest) showed several Tissues and Fluids taken from Tuberculous Patients, which had been stained by Ehrlich's method, and in which the bacilli were present in considerable numbers. He also demonstrated the manner in which he had prepared them.

Mr. Lucas exhibited a Liver affected by malignant disease which had originated in the lesser omentum and spread along the bile-duct, causing total obstruction and extreme jaundice. The liver had undergone no enlargement, and the patient had shown no sign of impairment of nutrition.

YORK MEDICAL SOCIETY.

THE ordinary meeting of this Society was held on December 9th, 1882, Mr. W. H. Jalland in the chair.

Mr. Jalland made some remarks on two cases of Excision of the Knee treated by him at the York County Hospital. Both patients were shown. The results were satisfactory. In one case the patient was up within a month of the operation.

Mr. Jefferson read notes of a case of Pernicious Anæmia. The patient was fifty-two years of age. He stated that for six months before admission to the York County Hospital he had suffered from severe epigastric pain which kept him awake at night, and that for two months he had vomited after meals. When admitted he was feeble and emaciated; his expression was indicative of suffering, and he complained of severe pain at the outer border of the left rectus on a level with the umbilicus. There was no tumour or enlargement of any of the organs. His urine was normal. The case was thought to be one of malignant disease. A pill containing morphia, creasote, and nuxvomica was ordered, and after ten days the vomiting ceased. Citrate of iron and quinine were then given with cod-liver oil. In fourteen days he gained sixteen pounds in weight, and within a short time an additional stone. He returned to work and has had no relapse.

Mr. Clifford Gill showed some sections of Cancer of Bone. The patient from whom the diseased bone was taken was an elderly woman, who for many years had been insane. A tumour was noticed in the neighborhood of the sacro-iliac synchondrosis, and this when removed had attained the size of a Maltese orange. Shortly after the appearance of this tumour, a small scirrhus tumour of the breast was detected. On examination under

the microscope the bony tumour was found to present the characteristic cancerous arrangement.

Mr. Spencer read some remarks on Acute Rheumatism. As illustrating the connection between acute rheumatism and erythema multiforme, he took three cases. Those of two young women between sixteen and twenty, and that of a man aged forty. The women were fair-complexioned and anæmic, the man dark and anæmic. In each case there was a period of invasion, and, in two, sore-throat during this period. In all these the attack followed on a chill, the erythematous rash commenced by distinct papules on the hands and feet, and the urine was turbid and deposited urates copiously. In one there was no affection of the joints. In the other two many joints were affected. After some allusion to the remarks of Trousseau, Bristowe, Powell, and Thin on the subject, Mr. Spencer referred to a case brought before the Society last session by Mr. Jefferson, where the order of symptoms was: firstly, pericarditis; secondly, erythema papulatum; and, thirdly, acute rheumatism.

Mr. Spencer then read the following notes:—A young delicate girl, sixteen years of age, who had suffered from chlorosis for some time, was exposed to wet and cold. Four days afterwards she began to suffer from synovitis of the ankle-joint. The general symptoms were slight, and there was no febrile disturbance. On the following morning, when rising from the sofa, she fell backwards in a fainting condition, and soon afterwards died. On post-mortem examination the walls of the heart were found to be thin, the valves normal, and the foramen ovale patulous. A laminated fibrinous mass, which was partially adherent, occupied the apex of the left ventricle, and a quantity of translucent fibrin, possibly of post-mortem origin, extended from the superior vena cava into the right auricle through the patent foramen ovale into the left auricle, and through the mitral orifice into the left ventricle which it nearly filled. Mr. Spencer discussed briefly the question of the essential nature of acute rheumatism, referred to the zymotic and chemical theories of its etiology, and, finally, pointed out its relationship to gout, in which disease a poison or poisons manufactured by perversion of a normal process is known to be the predisposing cause.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

A meeting of this society was held on Dec. 21st, 1882, Mr. B. Walker, President, in the chair.

Mr. Gubbins exhibited specimens from a patient in whom existed Complete Absence of Left Kidney and Supra-renal Capsule, Rudimentary Left Lobe of Liver, etc. The patient, a man aged twenty-four, had been under the care of Dr. Branson, in the Sheffield Public Hospital, where, on Nov. 16th, he had been admitted, suffering from anæmia, following a severe attack of hæmatemesia. The vomiting of blood recurred several times, and he died at the end of a fortnight. The patient had been in India for two years and a half, had drunk freely, had several attacks of ague, and had been discharged from the army for enlarged spleen. At the post-mortem examination the following condition of parts was found:—The liver weighed 2lb. 6 oz., and consisted almost entirely of the right lobe; microscopical examination showed moderately advanced cirrhosis; the spleen weighed 2 lb. 2 oz., and was tough on section; the right kidney weighed 13 oz., but was otherwise normal in appearance. The left kidney was entirely absent, neither was there supra-renal capsule nor ureter; there were many pints of clear

fluid in the peritoneal cavity; the lungs were healthy; the heart weighed 14 oz.; there was only one ridge and one opening (right) in the bladder; there was no malformation of any part of the genital organs discovered. Mr. Gubbins remarked on the interest attaching to this case from the absence of the left kidney and supra-renal capsule, as well as the rudimentary condition of the left lobe of the liver, and said that in 1878 Dr. Brenner (*Virchow's Archiv*) had collected records of forty-eight cases of congenital absence of one kidney; but in all these cases, except five, the supra-renal capsules were present. Dr. Brenner also stated that in one-third of his series of cases there was some malformation or arrest of development in one or other of the genital organs.

Dr. Dyson exhibited the morbid specimens from a patient who had suffered from Ovarian Cystic Disease. The woman, aged thirty-five, was delivered of a weakly child two weeks before her death. The cyst was simple, unilocular, and filled with pus; it was tapped a fortnight before death and eleven pints of pus removed, but had rapidly refilled. The patient suffered from capillary bronchitis and pneumonia ever since her confinement, and this, together with great exhaustion, had never permitted an opportunity for ovariectomy. Some recent peritonitis was present in various situations, but in each of them at a considerable distance from the trocar wound, which was quite healed. A great point of interest in the case was the condition of the lower lobe of the left lung; this was small, very tough, and fibrous; the bronchial tubes, both small and great, were dilated, and in many instances cretified. The breath of the patient during life was peculiarly offensive.

Dr. Keeling related the particulars of a case of Puerperal Tetanus. With the exception of some flooding, to which the patient had always been liable in her confinements, parturition in the present instance was normal, and had been followed by a satisfactory recovery up to the tenth day. Symptoms of lock-jaw manifested themselves on the eleventh day after labour. The patient died in a paroxysm of apnoea three weeks after her confinement, and on the ninth day after the first appearance of tetanus.

Mr. A. Jackson exhibited a Portion of Catheter removed from the Male Bladder by him the same day by the ordinary lithotomy operation. The piece of flexible catheter was thickly coated with phosphates.

Mr. E. Skinner related particulars of a case of Retroversion of the Gravid Uterus. The patient, aged nineteen, was in the third or fourth month of pregnancy, and was on September 10th suddenly seized with abdominal pains and feelings of faintness and sickness. Later on, a midwife detected a hard swelling at the mouth of the vagina; and on September 15th Mr. Skinner first saw the case. The patient was then suffering great pain, the abdomen was distended, and she was pale and faint. He detected at the orifice of the vagina a firm round tumour about the size of an orange, pressing upon the perineum and descending the anus; this was the fundus uteri, and the os was situated above the pubes. An attempt to pass a catheter along the distorted urethra failed, but later in the day was successful. No urine had been passed since the 10th. Attempts at replacing the uterus caused such distress that they were not persevered with then, but later in the same day, when the bladder had been emptied, with the patient in the knee-elbow position, it replaced itself without difficulty. On the 17th there was recurrence of pain and distress, and the uterus was again found to be retroverted. It was again replaced, and a Hodge's pessary introduced to

support it. On the 18th she was delivered of a four months' foetus, and made a good recovery. Mr. Skinner stated also that, a month later, he found retroflexion, which he replaced, and for which she still wears a pessary.—In the discussion which ensued, Dr. Keeling, Dr. Martin, Mr. Jackson, and Dr. Dyson took part.

ACADEMY OF MEDICINE IN IRELAND.

OBSTETRICAL SECTION.

At the meeting of the Section on Dec. 22nd, 1882, the President, Dr. Denham, delivered his opening address, taking for his subject the Progress made in Obstetric Medicine during the Last Fifty Years. He selected as the basis of his remarks a comparison of the Rotunda Hospital Reports of Drs. Collins and Shackleton with those recently published by Dr. George Johnston. Dr. Collins during his seven years' Mastership had 16,414 deliveries, in which the crotchet was used 118 times and the forceps or vectis 27 times. The number of deaths amounted to 164. Dr. Shackleton reported 13,748 deliveries, with the use of the perforator in 130 cases and of the forceps in 200 cases, and the loss of 163 patients. Dr. Johnston reported 8,908 deliveries; 28 craniotomy, 90 version, and 750 forceps cases. He lost altogether 169 patients. Commenting on these figures Dr. Denham observed that it was patent that by the more frequent use of the forceps in modern obstetrics much had been done for relief without adding to the dangers of labour, and that great numbers of children were now delivered alive who under the old practice would have had to be destroyed. The beneficial results of the introduction of chloroform, the greater use of sea-triangle tents, the operation of ovariectomy, followed as it has been by so many new operative procedures, were briefly alluded to as having done much to bring gynecologists into the front ranks of bold and successful operators, and to break down the barrier which at one time existed between this and other branches of the profession.

Mr. Arthur Benson exhibited a male patient showing a well-marked example of recent Spontaneous Detachment with Rent in the Substance of the Retina.

Dr. G. F. Duffey showed the Heart and Pericardium of a male patient, aged fifty, exhibiting the recent pathological effects of an acute pericarditis which had lasted only for about eighteen hours.

Dr. Roe exhibited a series of Frozen Sections which he had lately made:—(1) Section through medial horizontal plane of foetal head; (2) section through the shoulder-joint and upper part of the chest; (3) section through the level of the third costal cartilage.

Dr. Poole showed, for Dr. Kidd, two Dermoid Ovarian Cysts removed from an unmarried patient, aged thirty-eight. The growth of the tumour had been noticed for three years. The larger tumour involved the left ovary, and weighed on removal about 6 lbs. It consisted of numerous loculi of various sizes, some containing glairy mucoid fluid, and others masses of sebaceous matter mixed with hairs. Hard centres of ossification were felt in a portion of the cyst walls; one of the larger cysts contained a matted mass of long dark hairs, on removing which a mass of bone was found jutting sharply into the cavity, and bearing on its apex two closely united teeth. The smaller tumour belonged to the right ovary, and consisted of two cavities, one containing sebaceous matter with a few hairs, and in one part of its walls a mass of bone; the other contained a quantity of light-

colored hair and several teeth irregularly set in a bony wall.

Dr. Neville exhibited a specimen of Fœto-amniotic Adhesions, associated with numerous Deformities of a Full-time Fœtus, including complete Ectopia of the Abdominal Viscera, and with it a four-months fœtus, around whose right forearm the funis had become looped and adherent, associated with deformities of both hands, etc.

Dr. More Madden read a paper on Cicatricial Occlusion of the Vagina. Clinical experience of retained menstruation or impeded parturition, consequent on post-partum adhesions of the vaginal walls, is, he said, fortunately more limited than must have been the case formerly, when the second stage of labour was frequently allowed to run on for twelve or even twenty-four hours, and when instrumental assistance was directed by the most eminent authorities to be withheld until the vital powers were all but exhausted. Still such cases are occasionally met with. Of somewhat greater frequency in the causation of this condition in modern practice is the opposite error of premature application of the forceps before the natural dilatation of the passage, or by the misdirected force or undue haste with which instrumental extraction may be effected. Another source of such occlusion is the abuse of escharotics for the treatment of uterine disease. Apart from these causes, the occurrence of vaginal occlusion after parturition is exceptional. A case of this kind recently came under his care in the gynecological ward of the Mater Misericordiae Hospital. The patient, married, aged thirty-eight, had given birth to four children. She never had any difficulty in parturition, and her recoveries were always rapid. Six months before admission she had a miscarriage on the fourth month. This was caused by over-exertion, and presented nothing peculiar. Up to this time her general and uterine health had been excellent. Two months after miscarrying she began to complain of obscure pelvic pain, with sense of local fullness and bearing down. Her menses did not return, and as she had previously been very regular in this respect, she naturally supposed herself to be again pregnant. The pelvic pain increasing, however, and being now attended with dysuria, troublesome tenesmus, and obvious impairment of her general health, she sought medical advice. When admitted into hospital, the pelvic cavity was found to be filled by a large globular tumour, which extended backwards so as to flatten the rectum against the sacrum, and upwards and forwards so as to displace the bladder. The entrance to the vagina was thus obstructed, so that the finger could only be passed in for an inch and a quarter. On bi-manual recti-abdominal exploration, the uterus was found enlarged to the size of the fourth month, but in its normal position. The patient was then placed in the lithotomy position, the parts widely separated by retractors, and the seat of the obstruction was seen to consist of a tense, convex, fibrous-looking septum. This diaphragmatic-looking cicatricial structure was punctured with a fine trocar, and a small quantity of retained menstrual fluid drawn off by the aspirator. As the fluid was too viscid to pass freely through the cannula, the aperture was enlarged so as to admit the point of the finger, with which it was torn through so as to allow the gradual escape of about eighteen ounces of thick, treacle-like, catamenial matter. For two days afterwards this continued to drain away, and probably as much more escaped in this way. The membranous partition described formed the floor of a large hour-glass-shaped cavity, the lower part of which was bounded by the distended vaginal walls, communicating

through the open os and expanded cervical canal with the dilated uterine cavity which formed its upper and smaller portion. On the day following the operation she had rigors, her pulse and temperature ran up, the abdomen became tympanitic, there was considerable uterine pain and tenderness, and for the ensuing week her life hung in the balance from severe metro-peritonitis. This, however, ultimately subsided under treatment. The opening was then cautiously and gradually expanded by dilators, and kept patulous by glycerine tampons until all trace of constriction had disappeared. She was retained under observation until the next monthly period, which was perfectly normal, had passed over, and being then well, was discharged from hospital. The treatment of cicatricial vaginal obstruction is by no means as safe as it is facile. And the safest instrument in the removal of these adhesions is the surgeon's finger—the mortality following the use of any cutting instrument being nearly threefold that resulting from their digital separation.—Dr. Athill said that the case was unique in his experience. He did not think that the occlusion could have resulted so completely from any abuse of caustics. It was probably due to the occurrence of adhesive inflammation, such as he had seen result in a like way in the case of women who had never been pregnant.—Dr. Kidd narrated the history of a case recorded by the late Dr. Sawyer, in which a cicatricial occlusion of the vagina was found as an impediment to labour at the end of her second and third pregnancies, the occlusion having on each occasion to be opened up by crucial incisions. He insisted on the impossibility of negating the co-existence of pregnancy with almost any amount of occlusion.—Dr. J. A. Byrne thought atrophic contraction was limited to older women than Dr. Madden's patient. Strong escharotics injudiciously applied were, he thought, among the most frequent causes of vaginal or cervical occlusion. When retention of the menses resulted, they should be let out slowly and cautiously.—The President thought that conception might occur in spite of very considerable occlusion. Occlusion did not seem to be so frequently met with now as when the forceps was less often and more tardily used.

Dr. Neville read a paper on Breaking Strain, or Tensile Strength of the Umbilical Cord, founded upon 125 experiments made by him on the fresh cords of full-time children. Having explained the method of making these experiments, in which only the 12-14 inches of the cord nearest to the placenta were tested, he stated his conclusions as follows:—In 100 cords from which the blood had been allowed in great part to escape before subjecting them to strain, the average tensile strength amounted to 12.5 lb.; one cord bore a strain of 27 lb.; nine cords a strain varying from 20 lb. to 25 lb.; eighteen of from 15 lb. to 20 lb.; forty-eight of from 10 lb. to 15 lb.; twenty-three of from 5 lb. to 10 lb.; and one of less than 5 lb. In the case of twenty-five cords tested without allowing any escape of the blood contained in them, the average breaking strain was found to be very little above 11 lb., or nearly one and a half pounds less than in the other case. The cords belonging to male were found to have an average strength of 1.5 lb. more than those of female children; multiparity made no appreciable difference in strength. Dr. Neville considered the question of a gradual drag as affecting inversion of the uterus. Assuming as conditions a strong funis abutting at or near the centre of the fundus on a firmly adherent placenta, and a flaccid pliable uterus wanting in contraction and retraction, he thought improper tractions on the cord very likely to terminate in inversion.—

Dr. Macan considered that there could be no doubt that inversion might readily be effected by pulling on the cord under the circumstances laid down in the paper. He would lay special stress on the fact that traction, in order to result in this way, should be made at right angles to the uterine wall, at the site of placental attachment. This only could happen when the placenta had a fundal attachment.—Dr. Atthill compared inversion as an accident of delivery with that which resulted from an intra-uterine tumour. In the one case he believed that, as a matter of personal observation, the tumour, and in the other case the placenta, would always be found attached to the fundus. The fundus was the part of the uterus most susceptible of irritation. Irritation would set up contractions, and these would expel either the tumour or placenta, and along with either might invert the uterus. Pulling on the cord might facilitate the inversion, but could not act as a sole cause of this accident.—Dr. Neville did not reply.

Dr. J. R. Kirkpatrick exhibited a specimen of a Mummified Fœtus, with the Placenta and Membranes belonging to both children, of a pregnancy which had gone to full time. There was a single placenta and double membranous sac, that portion of the placenta which belonged to the mummified fœtus being shrunken and degenerated. The fœtus appeared to have died about the sixth month, and to have been since retained without occasioning any pathological symptoms. It was first born, after which the other child presenting by the shoulder was turned and born alive and healthy. The living child, a female, weighed 8 lb. The placenta was quickly afterwards naturally expelled. The mother was a healthy multipara, aged thirty-three years, her six previous labours having terminated normally.

Editorial.

ON OSTEOMALACIA IN CHILDHOOD.

It will be remembered by those who attended the Section for Children's Diseases of the International Medical Congress of 1881 that Dr. Rehn, of Frankfort, showed a remarkable specimen of extreme softening of the whole skeleton of a child. Along with some signs of rickets there were also indications of osteophytes, very similar to those described by M. Parrot as characteristic of congenital syphilis. We regret not to find a full account of this remarkable specimen in the Transactions of the Congress. Dr. Rehn has, however, followed up the subject at a recent meeting of a Medical Association held at Eisenach, and his cases there recorded are worthy of careful consideration.

The first is that of a girl aged sixteen months. She was a miserable child, with some undoubted signs of rickets, very considerable beading of the junctions of ribs with the costal cartilages, and bending in of the ribs beyond. The scapulae were thin, and the infra-spinous portions bent in. The clavicles between the first and second thirds were also bent, and so were the radii and ulnae. The bones of the forearm, the humeri, the femora, and one tibia were thin and easily bent. The connecting zone of diaphysis and epiphysis in the long

bones was inconspicuously marked, and the lower extremities were quite straight. The spleen was not enlarged, and there was no pyrexia. The child had been nourished with what is called "ordinary milk," and had lived in an unhealthy home. With the administration of better milk there was marked improvement. The child, however, succumbed after a month or two to an attack of capillary bronchitis. The right tibia and radius were submitted to Von Recklinghausen for examination. The tibia showed to the naked eye trabeculae of osteoid substance, which could easily be cut; it occurred principally in periosteal deposits, especially on the middle of the diaphysis, but also within the spongy axial substance, as well as in the bone cortex. A rachitic zone was to be made out at both ends. Various measurements are given, of which the most important is that the thickness of periosteal deposit about the middle of the shaft was nearly four times as great as that of the compact layer of the bone cortex. The radius was bent in its middle, and formed an angle of 120°; a fracture was not recognizable; still the flexibility was at this point at its greatest. At the bent spot the medullary canal was completely wanting, and the bony substance was quite uniform and finely porous, being made up of trabeculae of osteoid substance, and leaving only faint traces of the old bony cortex to be recognized. On the side on which the angle of the bend opened an especially marked periosteal layer was present. There was a rickety zone at both ends of the radius, which showed microscopically the characteristic proliferation of cartilage cells. Von Recklinghausen ultimately came to the conclusion that the essential characters of the case were those of osteomalacia, the bone trabeculae being quite devoid of lime except in the cortical portion; and he considered that the rickety features were of secondary importance. In none of the other four cases recorded was an autopsy obtained, and it will serve our purpose to give Dr. Rehn's general résumé.

Amongst prodromal symptoms, he mentions unrest, sleeplessness, and tenderness on movement—signs, in fact, which we are accustomed to associate with the oncoming of rickets. The extreme softness and flexibility of the long bones, as indeed of the whole skeleton, and the marked thinning of the bones, Dr. Rehn instances as the most important features; and he insists that the enlargements at the junctions of the shafts with the epiphyses were only moderate in amount or entirely wanting, at all events in the lower extremities. Fractures were frequently found. Cranio-tabes was present in two cases. The order in which different parts were affected in regard to intensity of disease was, first, the bones of the forearm and leg, then the humeri, and, last, the femora. As respects other symptoms, diarrhoea was not present in any one of the cases, splenic enlargement occurred in three, and in all there

was a high grade of anæmia and emaciation. In no case was pyrexia present. Profuse sweats occurred often. The urine showed no increase in earthy phosphates, except in one doubtful observation. The course of the affection lasted over several months. Three, perhaps four, recovered; and the two who died succumbed to respiratory troubles.

In regard to etiology, Dr. Rehn's observations are very meagre. The age of the patients—the first and second years of life—he gives as predisposing causes, and remarks on the fact that all his cases were of the female sex. He assumes that an insufficient amount of phosphoric acid and lime salts in the food-supply must be the proximate cause of the malady, but does not venture further than to quote Roloff's well-known experiments on the induction of osteomalacia in animals.

As to diagnosis, Dr. Rehn, admits that there is an osteomalacia associated with hereditary syphilis, but says that none of his patients had any sign of the latter malady. Nevertheless, as all the cases came first under observation at the age of one year or upwards, it is open to doubt whether hereditary syphilis could be absolutely negated. It is certain that many syphilitic children, especially when hand-fed, pass into a state of extreme marasmus, in which there may be considerable splenic enlargement, the pathognomonic signs of syphilis having disappeared. With regard to the distinction of these cases from examples of rickets, Dr. Rehn maintains, as we have before said, that the swellings at the junctions of diaphyses and epiphyses were moderate or slight in amount, and especially in the lower extremities, were sometimes entirely absent, whilst the softening was always a striking feature. Further, he considers the thinness of the whole skeleton and straightness of the lower extremities characteristic of the infantile osteomalacia. The excessive tenderness on movement, and in some cases pseudo-paralysis, he says, attained a far higher degree in these cases than in any examples of true rickets which he has seen.

The prognosis of the infantile osteomalacia, Dr. Rehn points out, so far as can be learnt from these five cases, is more favorable than in the adult form of the disease. Good nourishment, and protecting the bones from injury, constitute the therapeutics.

We have given in considerable detail Dr. Rehn's observations, because at the present time the natural history of rickets and its allies is awakening renewed interest. Dr. Rehn does not refer to the geographical distribution of his cases, but it is interesting to remember that adult osteomalacia is not an uncommon disease in the Rhine country, not very far from which, at all events, these cases must have come. But we venture to think, with all respect to the great authority of Professor von Recklinghausen, who supports Dr. Rehn's view, that it must still remain an open question whether

these infantile cases should be put in the same category with adult osteomalacia. There is a mollities ossium, more or less generalized, associated sometimes with cancer, as osteitis deformans is also sometimes associated with cancer. It is also admitted by Dr. Rehn that osteomalacia occurs in some cases of hereditary syphilis. Dr. Rehn maintains that in his cases rickets was only a concomitant, but it may be held by some that in rickets the features of (1) enlargement at the junction of shaft with epiphyses, and (2) of softening of shaft, may coexist in varying proportions. It is certain that such is the case in animal rickets, in which also a third varying feature must be added—viz., the new formation of massive porous bone. A valuable test would be the bringing forward of an infantile skeleton in which there were no enlargements that could be found post mortem along the junction of the epiphyses and diaphyses, and in which there was nevertheless softening of the shafts. We are free to admit that in some of our museums in London there are infantile skeletons in which there are abundant bendings, fractures, and deformities, and some new porous bone, but in which the bending of ribs is almost nil; and it is possible that Dr. Rehn might claim these specimens as examples (though less marked than his first case) of osteomalacia. But these it must be remembered, are dried and varnished specimens, in which the soft proliferated cartilaginous material has shrunk and partly disappeared.

We have always been taught that a good working distinction between osteomalacia and rickets is that in the first there is softening—a quasi-decalcification—of already formed bone, and in the second a formation of new imperfectly developed osteoid material. In Dr. Rehn's case it is expressly stated that there was a considerable formation of soft periosteal deposit, and if these cases are to be admitted as true osteomalacia this feature must be added as a special manifestation in the infantile form.

Dr. Rehn frankly admits that amongst the gaps to be filled up is an account of the bone marrow. As far as we can gather from the few sentences given the description hardly conforms on this point with the typical appearances with which we are familiar in the adult specimens. Without committing ourselves to a definite opinion as to the nearest affinity, we quite admit that these cases deserve to be put into a sub-group apart from the ordinary form of the rickets of children. Besides the desiderata to which Dr. Rehn has referred, it is greatly to be hoped that the further progress of such cases may be noted. Recovery seems to have been satisfactory so far as it was traced, but one would like to know if in any of them subsequent growth is specially retarded. The natural history of some very curious stunted children, such as one shown by Mr. Dent last year at the Pathological Society, and one by Mr. Barwell during the present session, has never yet been

worked out. Some of these cases appear to have had good maternal nourishment, the bone changes probably dating from a severe attack of some acute disease. The hypothesis with regard to his case was started by Mr. Dent that there had been some form of osteomalacia subsequently recovered from, but inducing arrested growth. In regard to both experimental investigation and clinical observation it is clear that we have a great deal to learn about the bone changes of infancy, but in the meantime our gratitude is due to Dr. Rehn for his valuable contribution.

THE SIGNIFICANCE OF THE BACILLUS OF TUBERCLE.

ALTHOUGH only a short time has elapsed since Koch's important discovery of the bacillus of tubercle was made known, facts are being rapidly accumulated in support of the truth of that discovery; observers in various parts of the world are engaged in the work, and in drawing conclusions from the facts observed. The subject is now forming material for debate at the Medical Society of London, where Dr. Whipple introduced it in connection with a case in which the detection of the organism proved of great service in establishing a diagnosis; and we publish a paper recently read before the Society of Medical Officers of Health by Dr. Heron, detailing his experience in sixty-two cases of phthisis of dissimilar type, and amongst individuals of different classes. Much no doubt remains to be established, and in particular should caution be used in arriving at conclusions respecting the question of the communicability of phthisis from one human being to another, which is, after all, the most important issue arising out of Koch's experiments. This is the question which, long a matter of popular belief, must now be submitted to the most rigorous scientific scrutiny, and seeing how vast a revolution it would make in the care and treatment of tuberculous individuals, we must not be content with anything short of actual demonstration of the fact of contagion. The discovery of the bacillus was not indeed a fact which was unexpected by pathologists. The whole pathological history of tuberculosis—its mostly local origin and frequent general diffusion throughout the body—pointed to its infective character, and a virus was assumed to exist years before it was associated with the presence of a definite micro-organism. The doctrine of Buhl, that miliary tuberculosis in a majority of cases resulted from the infection of a caseous focus, received greater significance when experimenters, as Villemin, Wilson Fox, and Sanderson, tested it by the inoculation of tubercle upon the lower animals, albeit their experiments proved too much in showing how prone rodent animals were to such disease upon the slightest irritation. Further, Cohnheim a few years ago fully and freely adopted the

doctrine of the infectiveness of tuberculosis, applying it not only to the possibility of the transference of the disease from man to man, but from animals to man—a conclusion which was further encouraged by such writers as Creighton, who advanced arguments in support of the transmission of bovine tuberculosis to the human species, through the consumption of the flesh or milk of the diseased animals. Thus, neither Baumgarten's work, nor that of Koch, came upon a world unprepared to accept their teachings. The conclusive and brilliant research of Koch was accepted all the more freely because it seemed to be the natural outcome of the slow growth of pathological inquiry upon the disease.

Pending the progress of the debate at the Medical Society it would hardly be advisable to enter fully into all the bearings of the subject, but there are a few points which seem to be fairly well established as arising out of the presence of this organism in tubercular material, points which were ably dealt with by Dr. Whipple and the speakers in the debate. The first of these is as to the nature of phthisis. All observers unite in saying that the bacillus is never present in the sputum unless the case is one of phthisis. For a generation and more the whole attention of pathologists has been directed to the subject of the nature of a disease that appears under so many forms, runs so varied a course in different cases, and presents such a complexity of lesions after death. Lænnec's criterion of tubercle, the tubercle corpuscle of Lebert, the giant cell of Schüppel, have one and all had their day, nothing pathognomonic or distinctive being found in their character or source. Of late years, it is true, not only the French, but the German school has so far reverted to Lænnec's teaching as to have arrived at the belief in the underlying presence of tubercle in every form of phthisis strictly so-called, a view that ten years ago was advanced by Dr. Wilson Fox before the Pathological Society, and opposed by several able pathologists imbued with the teaching of Virchow. If the bacillus be the constant concomitant of tubercular disease—if, in other words, Dr. Koch's researches be accepted and confirmed, as they are being, then at last we have a criterion of tubercular disease which will tend to establish, as Dr. Green pointed out, the doctrine of the "unity of phthisis." In this respect also, then, just as with the infectiveness of tuberculosis, Koch's research comes to verify an idea that was being slowly arrived at by pathological histologists.

Another point of advance is the aid given in the diagnosis and prognosis of tubercular disease by this discovery. Dr. Whipple's case illustrated its value on the former head. The case was one of that class in which the symptoms of pulmonary mischief were almost in abeyance, albuminuria and diarrhoea being its prominent features. Moreover, there was almost an entire absence of pyrexia throughout, so that the thermometric indications

of tuberculosis were wanting. As the case progressed, a few indeterminate physical signs appeared in the lungs, and an examination of the sputum revealed the presence of bacilli. In such a case, where the tubercular disease was suspected, but not proved, the detection of the bacillus clinched the diagnosis, which the post-mortem examination confirmed by revealing not only extensive tubercular ulceration of the bowels and lardaceous disease, but also widespread softening tubercle of the lungs. A case the converse of this was mentioned by Dr. Yeo. It presented the symptoms and signs of acute general tuberculosis, but repeated examinations of the sputum failed in detecting the bacillus. The patient died, and the lesions of typhoid fever were found, together with much bronchitis and pulmonary congestion, but not a trace of tubercle. Drs. Whipham and West both instanced other cases in which the absence of bacilli from the sputum accorded with the absence of clinical evidence of phthisis. Very interesting are the statements made as to the importance of these bacilli in prognosis. Drs. Heron and Gibbes have already pointed out that in the more rapidly progressive cases the bacillus is found in the sputum in great numbers, whereas in the more chronic forms it occurs quite scantily; and precisely the same observation has been made by Drs. Whipham and West, as well as by Balmer and Fraentzel. Dr. West supplied an explanation for this in the fact that the bacillus abounds in the caseous lining and contents of the pulmonary cavities, and may, therefore, be expected to be very abundant in the sputum in cases of rapid softening. This fact is one which deserves considerable attention, as bearing upon the supposed causal relation between the bacillus and the disease. We have yet to learn whether the very earliest stages of the disease are recognizable by the presence of the bacillus, and it is very interesting to learn from Dr. Whipham that in cases where the disease is arrested or is improving under treatment, they may be absent altogether. To clinical observations like these we require the addition of multiplied research into the diseased structures, and the bacillus must be found in the minutest granulation before assigning to it all the importance which is claimed for it.

The last point we will touch upon at present is the one to which we have already adverted as being by far the most important subject of all. What bearing has the discovery of the bacillus upon the doctrine that phthisis is contagious? The subject is one which is beset with difficulty, and most of us will agree with Drs. Whipham, Green, and West in approaching it with the greatest caution. For as Dr. Green pointed out, and as Dr. Richardson most strenuously urged, all that we know of consumption clinically is opposed to the notion. At any rate, there are other factors at work, such as an inherited tendency to the disease, and individual habits and surroundings

favoring its development, all of which have to be taken into the reckoning. Even looking at the subject from a wider point of view, and dealing with pulmonary phthisis as but one of many manifestations of tuberculosis, are we any nearer a solution of the question? Assuredly not; it yet remains to be proved that tuberculosis is contagious in the ordinary sense. Save in a few cases of almost direct breath-to-breath inhalation, we doubt if one practitioner in this country would affirm the proposition. Dr. Richardson said that in all his experience he had not seen one case that afforded support to this theory, and rightly pointed out that families predisposed to the disease and exposed to the infection, would be decimated on the development of a single case in their midst if the disease were contagious. The probability is that it will never be proved to be contagious in the ordinary sense—a view which by no means denies the truth of the facts as to its communicability by inoculation, which, as we have endeavored to show, are supported not only by the experiments of Koch, but by accumulating knowledge of the nature of tuberculosis. Let the fact of the inoculability of tubercle be first proved clinically, if it can be, before venturing to deal with the question of contagion at large, with all that would follow from the acceptance of the latter.

At present it may even be going too far to compare tuberculosis with such inoculable diseases as vaccinia and syphilis. Vaccinia is a disease in the virus of which a specific organism has been found; of its inoculability there can be no question, but of its spread by aerial contagion there is equally no ground for belief. Syphilis has even closer analogy with tuberculosis, but it is not contagious save by the direct transference of its virus. Is it not probable that the tubercular virus is conditioned by similar limitations, to which may also, in the majority of cases, be added the existence of other factors, of which there is danger of losing sight in the premature adoption of one narrow view?

VIVISECTION IN MANCHESTER.

THE views of persons possessed of common sense, to say nothing of those of scientific men, in the matter of vivisection have had a triumph in Manchester, which cannot long be delayed elsewhere. A great Anti-vivisection meeting was called by the International Association for the Total Suppression of Vivisection, and the resolutions proposed were rejected by constantly increasing majorities. The last one, barring a vote of thanks to the Chairman, was supported by only four hands. The three resolutions of the International Association and their fate are as follows:

"The Rev. H. N. Oxenham moved, 'that the practice of vivisection is directly opposed to the elementary principles of justice and morality implanted by a beneficent Creator in the hearts of men.'"

An amendment by Professor Arthur Gamgee was

decided to be irrelevant by the chairmen (Mr. J. B. McKerrow), who said that it had been determined, whatever happened, to put all the resolutions to the meeting. The resolution, being put, was lost, according to the report in the *Manchester Times*, "by at least twenty votes to one." The second resolution, equally characteristic, and moved in an equally characteristic speech by the Rev. W. A. O'Connor, was to this effect:—

"That the practice is not only immoral in itself, but necessarily tends, as is proved by professional evidence, to demoralize those who witness or take part in it."

This was lost says our contemporary, by an even larger majority than the former. The last resolution saving one of thanks to the chair, was—

"That vivisection may be shown, on the highest medical authority, to be useless as an instrument of scientific discovery, while it has served to suggest and perpetuate grave scientific error."

Only four hands were held up for this resolution. The discomforture of the anti-vivisectionists was complete. Of course they have a ready explanation—"The unfortunate absence of any experienced practical physiologist on their side"—(by the way, was there ever a meeting with an experienced practical physiologist on the side of the anti-vivisectionists?)—"the meeting was packed by medical students, etc., etc."—as if a public meeting in Manchester, called by the anti-vivisectionists, of 800 or 900 people could be packed by medical students. The result is far more easily accounted for. We unhesitatingly apportion the credit of the result equally in three directions: first, to the dignified statement of Professor Gamgee, characterized by scientific accuracy, by humanity, and by moderation; secondly, to the fanaticism and recklessness of the speeches of the promoters of the meeting; and thirdly, to the common sense of the people of Manchester, who are at once too shrewd and too religious to doubt that man is of more value than many rabbits and dogs, and that if the supreme right of killing and eating animals be allowed, it must carry the right—humanely exercised—of using them for experimentation that may conduce to the saving of human life. The power of Professor Gamgee's speech was chiefly in showing how sparingly and considerably the right of vivisection is used in England. He said he was convinced that during the last year in England there had not been twenty animals which had been put to pain in all the physiological laboratories put together. This statement was rudely used by one speaker, but it was not seriously refuted. We are sorry to notice that reverend gentlemen took charge of the extreme resolutions, and said the most absurd things about scientific men. They should really remember their own doctrines—to speak evil of no man; and especially to cultivate, if not a little charity, at least a little accuracy of statement, when traducing men who in the estimation of the public are as humane and religious as themselves.

PROFESSOR GRAHAM BELL'S EXPERIMENTS ON THE DETECTION OF METALLIC MASSES IN THE HUMAN BODY BY THE INDUCTION BALANCE.

Our readers will remember that an attempt was made to determine the position of the bullet in the body of the late President Garfield by means of an induction balance; it was, however, only partially successful, in that it afforded no evidence in support of the belief of the attending surgeons, that the bullet had travelled down on the right side, and at the same time failed to indicate where the ball really was, on account of its being placed at such a great depth from the surface. At the annual meeting of the American Association for the Advancement of Science held last August in Montreal, Professor Graham Bell read a paper in which he described the series of important experiments and researches which he had made with a view to render this instrument of real service to the surgeon in cases of gunshot wounds.

After referring to the discovery of the induction balance in 1841 by Professor Dove in Germany, and to the improved form of it invented by Professor D. E. Hughes, Professor Bell describes the simple form which he at first used. This consisted of two flat spirals of insulated wire, through one of which a rapidly interrupted voltaic current was passed, while its field of induction was examined by means of a telephone attached to the other; the currents induced in the latter producing a musical tone in the telephone. At every point in the field of induction, it was found that by turning the plane of the exploring coil a position of silence and another of maximum sound at right angles to it could be obtained. When the coils were in a position of silence, a piece of metal brought within the field of induction caused the telephone to sound; this effect was most marked when the spirals were in close proximity, and arranged with their planes parallel. The sound was most intense when the metal was brought over the spot where the two spiral coils overlapped.

Many suggestions as to the best form of construction of a practically useful induction balance were offered and tested, and numerous original experiments were undertaken by Professor Bell, which are all detailed in the paper before us. From these he learned that a better result was obtained by making the primary coil of greater diameter than the secondary, and by projecting the plane of the secondary considerably beyond that of the primary. It was further found advantageous to use a battery of great electro-motive force and slight internal resistance, and to connect the cells in series. At the suggestion of Professor Rowland a condenser was introduced into the apparatus, and it was found that this not only produced a different quality of sound, but also increased the hearing distance of the instrument. The problem then revolved itself into the construc-

tion of the most serviceable induction balance, and after many trials Professor Bell returns to his original form of two flat spirals, which he places in a recess turned out of a single block of wood; the coils are then temporarily connected with a battery, rheophore, and telephone, and are adjusted to the position of silence; the hollow in the wood is then filled with melted paraffine, and, on cooling, the coils are immovably fixed in a solid cake of this material. Practically, it is found to be impossible to fix the coils in their position of complete silence; but this is secured by introducing two other small coils of insignificant resistance, by means of which a kind of fine adjustment is obtained and a perfect balance easily secured. Metal may be introduced into this apparatus provided it is not placed over the spot where one coil overlaps the other. With this form of instrument President Garfield was carefully examined. No telephonic sound was heard down the right side of the abdomen, where the ball was believed to be lodged; but, raised above the trunk, an area of feeble sound was observed, which turned out to be caused by the wire mattress upon which the patient was lying. This examination led only to a negative conclusion, that the bullet was not where it had been formerly supposed to lie, but was embedded in the tissues too deep to affect the balance; the autopsy showed this to be the case. On Oct. 7th further experiments were made on patients at the house of Dr. Frank Hamilton. In one case, a bullet which had lodged in the right antrum was readily localized. The other case, used for experiment, was more striking; it was that of a man who, during the civil war in 1862, received a wound from a ball which passed through the sternal end of the left clavicle, and was supposed to have lodged in the muscles under the superior angle of the left scapula, and the symptoms confirmed this view; eighteen months later an abscess formed on the chest, and opened below the fifth rib to the left of the sternum. In this case the coils were moved over that portion of the back where the ball was supposed to be, but there was no response; when, however, they were moved along the front of the chest, at once a "loud and distinct" response was obtained over an area of about one square inch. The ball was actually "found to be within the thorax, probably in immediate contact with the inner surface of the ribs, the point being a little to the left of the sternum, between the third and fourth ribs."

In every case the instrument is more sensitive to metal placed inside the exploring coil than outside, and an apparatus devised by Mr. S. Tainter permits of this being readily done. In his instrument the exploring part consists of one coil only, which may be made in the form of a large ring consisting of several turns of thick insulated wire, which can be slipped around a limb. All the adjustments are made upon the stationary part of the instrument. When this is used, the loudest sound

will be produced when the ball is in the plane of the ring, and if the ring is slipped up the limb in three different planes, and the positions of loudest notes marked, the point where these three lines intersect will exactly localize the bullet. A similar ring might be made, consisting of a double wire, and be used in the same manner. The drawback to this modification of Professor Tainter's is that it does not detect metal at so great a distance from the explorer as Bell's apparatus.

Professor Bell also suggests that, either for the detection of bullets or for the estimation of the depth of a ball already localized by the induction balance, a simple electrical contrivance may be employed. It consists of a telephone, to one terminal of which a fine needle is fixed, and to the other a plate of metal of the same nature as the needle. The plate is placed on a limb to be examined, and the needle is thrust in where the bullet is believed to be, and when it strikes the ball, a galvanic battery is formed within the body, the two poles of which are the bullet and the metal plate. This will cause a click to be heard in the telephone each time the bullet is struck. This is a far simpler apparatus than the induction balance, and one far more easily procured, and it would be well if surgeons called upon to treat cases of gunshot wounds would test its practical utility. Professor Graham Bell's efforts to apply electricity to practical surgery are most praiseworthy, and the results he has obtained merit the attention of surgeons.

Reviews and Notices of Books.

A Treatise on Surgery; its Principles and Practice.
By T. HOLMES, M.A. Cantab., Surgeon to St. George's Hospital. With 418 Illustrations. Third Edition. London: Smith, Elder & Co. 1882.

MR. HOLMES may fairly be congratulated on the fact that a third edition of his book has been so speedily called for. This is in itself sufficient evidence that it is felt to meet the want of students. The literary ability of the author is acknowledged by all, and the style in which the volume is written is such as to justify his reputation. He has had, too, a long experience at St. George's Hospital, and is qualified to speak with authority on points of surgical practice; moreover, his position as a teacher, and more recently as an examiner, has made him well acquainted with the difficulties of students. This edition has been carefully and thoroughly revised, and while Mr. Holmes has forbore to introduce the novelties of surgical theory and practice, he has attempted to incorporate all those real and generally accepted advances that have been made during the last few years. As before, the work is well produced; it is clearly printed, on good paper, and the illustrations are both numerous and good. A strange error, however, has been allowed, evidently by inadvertence, to creep into one of them. On page 843 a woodcut to illustrate the operation of tapping a hydrocele is introduced, and the surgeon is represented as holding the trocar in his left hand. Mr. Holmes

speaks in no ambiguous terms of the value of Mr. Lister's mode of treating wounds. These are his words: "I cannot but express my own strong conviction of the value of the method of dressing wounds which Mr. Lister has introduced. I have frequently ascertained by thermometric and other observations, and pointed out to others, the perfect immunity from traumatic fever which in some cases follows even the gravest injuries or operations thus treated. . . . and on that account I advocate the use of the system, as well as on account of its utility in hospital practice; for it necessitates the dressing of important cases by the surgeons or house-surgeons themselves, and almost excludes the possibility of any subsequent inoculation." The style in which Mr. Holmes has chosen to write his book appears to be not specially well adapted for precision of statement, and as we have glanced through the work some points in which this want of accuracy and incompleteness of detail have appeared to us important have arrested attention. We indicate them here in the hope that they may be remedied in a future edition. Thus in reference to the antiseptic treatment of wounds no stronger solution of carbolic acid than one in forty is anywhere mentioned, and this is recommended for the cleansing of wounds already made, and for use in the spray producer. The same lotion is also stated to be efficient for cleansing putrefying sinuses. The "six or eight" layers of antiseptic gauze applied as the dressing are stated to be covered "with a light macintosh cloth which surrounds and overlaps the whole, in order to prevent the discharge from saturating the gauze." The directions for securing free drainage are equally wanting in accuracy: "Drainage of putrefiable matters is therefore secured by insertion into the wound, in any convenient part or parts, of a drainage-tube, or a piece of lint, or skein of horse-hair rendered antiseptic by immersion in carbolized oil; but the drain must not project beyond the antiseptic dressing any more than the 'protective' must, otherwise they would serve to conduct the undiluted atmosphere to the wound." The "deep dressing" is nowhere mentioned at all. The proper mode of preparing antiseptic catgut ligatures is also a matter which Mr. Holmes does not describe. Iodoform is not mentioned as an antiseptic agent; even Esmarch's striking results are not recorded. This agent is now so widely used that the student may fairly expect to find in his surgical text-book some allusion to its mode of application and uses. Since Mr. Holmes is able to advocate the use of the antiseptic treatment, it is a pity that he did not describe all its details with more precision. We are surprised to find Mr. Holmes teaching that compound fractures "unite in a very different manner from simple;" for while it is no doubt true that they are often attended with suppuration, sloughing, necrosis, and other complications, yet there is no *essential* difference in the process by which the break in the bone is made good. Lymph is exuded in both cases; this lymph comes from the same tissues, and it organizes into bone in each case alike; and in very many instances either Nature or art converts a compound into a simple fracture. We would not conceal from the student the obvious and oftentimes important differences that are met with in some cases; but it is not of chief importance, at any rate at first, to insist on the *uniformity* of Nature's processes, and only after this has been realized to point out the variations which occur, most often as the result of preventable conditions? An omission and an evident oversight in this same chapter will not escape notice. Nowhere do we find any reference to the blebs which to the uninitiated appear so threatening in many cases of fracture.

Their frequency of occurrence and their innocuousness make them worthy of notice; while the fact that they are of use in enabling the surgeon to diagnose a fracture when complicated with great oedema preventing proper examination of a bone, clothes them with actual importance. The error is in the statement that among the disturbances of health which may cause delay in the union of a bone, "disease of the kidneys, leading to a phosphatic state of the urine," is common. Mr. Holmes does not require to be reminded that excessive excretion of phosphates is never due to functional or structural disease of the kidneys, but to excess of those salts in the blood; while in the majority of cases in which phosphates are deposited from urine, the cause is to be found in deficient acidity of that excretion. In discussing the question of the passage of foreign bodies into the larynx, Mr. Holmes expresses his conviction that this may occur during swallowing, "without an inhalation." In support of this view he cites two cases, one of which is that of an adult, who "got a large piece of rabbit bone into the upper part of the larynx in consequence of laughing whilst he was eating soup." This appears to us to be an excellent and typical example of just the reverse, for can it be doubted that the piece of bone was drawn into the larynx by the forced sudden inspiration which followed the succession of expulsive expirations constituting the laugh?

As another instance of ambiguity that should be remedied in the next edition we would refer to the description of the lesion in Pott's fracture: it is not distinctly stated whether the dislocation is complete or partial, but we can well believe that the student would understand the phrase, "the astragalus is separated from the tibia," as applicable only to a complete dislocation of the joint. We regret to see that the term "canceroid" is applied by Mr. Holmes to "locally malignant" tumours. Such a use of the term is likely to give rise to serious misunderstanding; for it was originally employed to designate epithelioma, and is now commonly used in that sense, especially by French and German pathologists.

The chapter on Diseases of the Breast appears not to have received such careful revision as some others, and to be hardly worthy of such a very important, and withal frequent, group of affections. The etiology of "lacteal abscess" is thus described: "The common cause of inflammation of the breast is irritation in suckling, and usually in women who persist in doing so when in too weak a condition to bear it. Its cause is often to be found in an imperfect development of the nipple. The woman is generally a primipara, and the abscess usually occurs within a month after delivery." Each of these statements is no doubt true, but yet we think they are so made as to convey a wrong impression to the student, if indeed they do not confuse him. A deformed or diseased nipple obstructing the outflow of the milk will lead to abscess usually early in lactation, and often of course in primiparae, but this form has nothing in common etiologically with that due to over-lactation, and which occurs most often after months of suckling. The stage of milk congestion which precedes that of inflammation and abscess, and the proper treatment of which is so successful in preventing the latter, is not mentioned, nor is the very useful power of belladonna to check the lacteal secretion referred to. Chronic abscess of the breast is described as only occurring at puberty; we have not been able to find any mention of it as associated with lactation or abortion, or occurring after puberty. Mr. Holmes has no doubt seen chronic abscesses occurring at puberty, or he would not have described them, but it has been our lot to

see only acute abscesses at that period, and these have been nearly invariably superficial to the gland, and just beneath the areola. And we can hardly believe that Mr. Holmes is not familiar with the small chronic abscesses occurring often long after delivery or abortion, in women later in life, which at times are so difficult to diagnose from malignant tumours. The importance of these is such that Mr. Erichsen gives a special table of diagnosis. Apart from this, however, Mr. Holmes has omitted to give any directions for the treatment of these chronic abscesses. Again, the subject of tumours of the breast is incomplete. The work of Dr. S. Gross appears not to have been appreciated by Mr. Holmes, as he gives only the imperfect pathology of more than ten years ago, and states that cancer sometimes occurs "in the form of a defined mass separated from the gland by a distinct capsule." The most valuable sign of cancer of the breast—its fixity in the gland—is omitted altogether, while prominence is given to that popular but unreliable symptom, "lancinating pain in the chest and neck and down the arm." In the discussion of the cases suitable for operation, the facts of the age of the patient, the variety of the cancer, and its rapidity of growth, all of them of prime importance, are not alluded to at all.

A Treatise on Diseases of the Liver, with and without Jaundice. By Dr. GEORGE HARLEY, F.R.S., F.R.C.P., etc. London: J. & A. Churchill. 1883.

To those readers and practitioners who are familiar with the works of Budd, Frerichs and Murchison on the Diseases of the Liver, this treatise will be a great surprise. We had become so accustomed to brevity and method, that we are hardly prepared to find the same affections treated in the discursive and sketchy manner which the author of the present volume has chosen to adopt. Instead of handy, closely-printed volumes, with the materials of the subject compressed into five or six hundred pages, we have now presented to us a large book of eleven hundred pages, with much marginal space, and the widest letterpress, containing Dr. Harley's views on the pathology, diagnosis, and treatment of the diseases of the liver, with any digressions in which it may please the author to indulge, and not a concise, well-reasoned, and orderly statement of what is generally known of such affections by most well-informed physicians of the present day. The work therefore is of value in showing us what the author thinks of liver diseases, and in what respects he differs from other observers who have given special attention to the same subjects. The author's motto, that "true science is the key to wise practice," is sound enough, but surely he goes very far in the statement that the class of "scientific physicians" who, in addition to the ordinary routine, have spent some time in a physiological and chemical laboratory, is as yet a very small one. For the clinical teacher and observer who may even be conversant with physiological chemistry, and who, looking at its changes during the past twenty or thirty years, may hesitate to follow Dr. Harley in his inferences, and may consider some of his conclusions rash and perhaps liable to modification in the near future, even if not at the present time, our author cannot too strongly express his scorn and contempt. Some twenty years ago Dr. Harley published a small monograph on Jaundice, in which he divided all cases into those due to obstruction to the passage of bile into the intestines and those due to suppression of the

secretion, and he laid especial stress on the presence or absence of the bile-acids in the urine in regard to the differential diagnosis between these important conditions. Observer after observer failed in applying his simple test to cases of jaundice, and were consequently often led into error. Now we find that the test has not always succeeded even in the hands of the author, and "practical" physicians are told that in a treatise like this, intended for practical medical men, it is of no use to talk to them about the mode of chemically detecting bile-acids, but their scientific brethren may avail themselves of Hoppe's, Neukommen's, or Hilyer's method. The last is roughly and too incidentally described to be of any real use. However, the reference to it in the Chemical Society's Journal, 1876, page 445, is of value to those who may wish to undertake such an analysis. It is just possible that in another twenty years some of the views so positively laid down in this volume may also require considerable modifications. We should like a distinct and logical statement of the experimental data on which the following theory is founded. "In the human body not only is starch rapidly transformed into sugar, but sugar into non-crystallizable fat, and fat again in its turn into crystalline cholesterolin." We question whether any scientific proofs of the latter part of this statement be forthcoming, and yet this is the pivot on which Dr. Harley mainly rests his treatment for the prevention of gall-stones. The practice may be a good one, but the method by which it is arrived at is unworthy of the name of science. In many respects the work is extremely interesting, and although digressions from the main subject occur in almost every chapter, we are never bored; and everyone who is anxious to know the views of an observer who thinks for himself and is unbiassed by the views of other writers, will read it with great pleasure. The illustrative cases are told in a most amusing manner, the remarks on the mistakes of other medical men are not wanting in vigor even if they are not always in the best of taste, and the digressions themselves are in every case distinguished by the style and personality of the writer. It is not often that in a medical treatise, ostensibly scientific from beginning to end, we find so little with which modern physiologists and chemists would agree, but to compensate for this we are amused with disquisitions on spelling reform, the distinctions between a chemist and a druggist, the differences between scientific and practical physicians, the position of the mercurialists and anti-mercurialists, the A 1 character of the author's champagne, the drink of the Fiji islander and the food of the Chinook Indians. These and many more quaint tales and opinions will be found in this volume as well as more rational and interesting opinions on hepatic diseases and their treatment. Every credit is due to Messrs. Churchill for the excellent manner in which the treatise has been printed and published, and the illustrations, especially the two chromolithographs, are worthy of much praise.

Manuals of Elementary Science: Physiology. By F. LE GROS CLARK. Pp. 143. Society for Promoting Christian Knowledge. 1882.

This is a sufficiently complete and accurate little text-book. We presume it is intended for the higher classes in schools and for those who desire to obtain a rudimentary knowledge of physiology. We notice, however, a few errors. Mr. Clark speaks of the red corpuscles as "disks or cells." The term cell should be dropped. Whatever the corpuscles may be, they are not cells. The esti-

mated three ounces for the capacity of each ventricle is surely a little too low. The veins are said to have coats that are feeble than those of the arteries, but this is not so. A large vein will require a greater pressure to burst it than an artery of corresponding size. These, however, are slight slips of the pen, and, on the whole, the description of each organ would be intelligible to any moderately educated person.

A Handbook of House Sanitation for the Use of all persons seeking a Healthy Home. By EARDLEY BAILEY-DENTON, C.E. Enlarged and Revised by his Son, EARDLEY F. BAILEY-DENTON, C.E., B.A. Oxon. 8vo, pp. 218. London: Spon. 1882.

Wholesome Houses; a Handbook of Domestic Sanitation and Ventilation. By E. GREGSON BANNER, C.E. 8vo, pp. 124. London: Stanford. 1882.

Lectures on the Science and Art of Sanitary Plumbing. By S. STEVENS HELLYER. 8vo, pp. 332. London: Batsford. 1882.

It is very remarkable how little the sanitary conditions of the houses in which we dwell have been the subject of consideration by the general mass of the people. The smart outside appearance of the house, and still more of the "desirable villa residence," the existence in it of water-closets and possibly baths, and the assurance that it is drained into the main sewer, and that the drains are trapped, are too often all that are considered necessary by the coming householder, without any steps being taken to ascertain that the site of the house is dry and wholesome, that the closets, etc., are of good construction, and in working order, and that the drains are well laid, efficiently trapped, and thoroughly ventilated. It is a melancholy fact that many of those to whom the building and fitting of dwelling-houses are entrusted are either profoundly ignorant of the principles of sanitary construction, or culpably negligent in their application. In too many instances, also, where the knowledge exists and its practical application is intended, the work is, we fear, entrusted to incompetent hands and carried out without efficient and intelligent supervision. The result is that the defects are only found out by their consequences as shown in the broken-down general health of the inmates of the house, or by an outbreak of diphtheria or fever. That this is no imaginary picture has been proved by the history of too many families. During the last twenty years much has been done to improve the general public health, and to enforce attention to the sanitary conditions of towns, but these measures have not as yet had much effect in awakening the bulk of the public to the necessity of individual watchfulness over the state of their homes with a view to detect the causes of disease as they become developed, and adopt the necessary measures for their removal. In this direction much useful work may be done, and Mr. Bailey-Denton's Handbook of Sanitation is a valuable contribution to the knowledge of what is required and how it may be effected. He explains the conditions required in a house to ensure it being healthy—the external, including site, drainage, and construction, and the various methods of removing and disposing of the refuse, liquid and solid—and the internal, under which come the water-closets, baths, and lavatories, with a description of the various traps in use to prevent the introduction of noxious gases, and the different systems of ventilation. The second portion of the book is devoted to the important subject of water—

its qualities, sources of supply, storage and filtration, and distribution. On all these topics Mr. Bailey-Denton gives a clear, intelligible, and, as it appears to us, an impartial account of the various systems in vogue, with a statement of their relative advantages and drawbacks, and his descriptions of the various arrangements are illustrated by excellent woodcuts, which render his remarks easily understood. We consider this book to be one well deserving the careful study of architects, sanitary engineers, and medical men, and worthy also of the attention of educated non-professional persons who take an interest in questions relating to the health of the people. It bears the impress of thorough knowledge, theoretical and practical, of the subject of which it treats.

Mr. Banner's work has been written avowedly with the same purpose as the preceding, that of showing how to make wholesome houses; but he has confined himself to two subjects—ventilation and house-drainage. In both of these he recommends the system which he has invented under the name of the Banner System, and appends numerous testimonials of its efficacy, and a list of some of the more important places where it has been successfully adopted. The book deserves to be well considered by those who have to decide upon the system to be adopted in fitting a house; but it must not be forgotten that it is an exposition of one system only, and should be studied in comparison with others. This construction of trapless water-closets appears open to serious objections, even with the perfect ventilation of the soil-pipe ensured by the "Banner system."

The third book on the list may be considered as complementary to the other two. It treats of sanitary plumbing, a branch of work highly necessary in carrying out the construction of wholesome houses. The lectures were originally delivered at the request of the National Health Society, and were intended for the instruction of the workmen in that branch of trade, but they are of a character to be useful also to the employers and to all who may be called upon to report on the sanitary condition of dwellings. The description of the mode in which the work ought to be done is evidently that of a man who thoroughly understands it, and who does not hesitate to show up the defective way in which it is too often executed. It cannot fail to be useful by enabling those interested in the sanitary state of a house to detect flaws which might be productive of serious consequences, and to judge whether the proper remedy is applied and the work satisfactorily carried out. The author concludes his lectures with a very brief but useful "Code of Rules for House-Sanitation." This volume and Mr. Bailey-Denton's have each the advantage of a carefully-prepared index.

A System of Surgery, etc. By SAMUEL D. GROSS, M.D., D.C.L. Oxon., LL. D. Cantab., Emeritus Professor of Surgery in the Jefferson Medical College. Sixth Edition, Two Volumes. London: Smith, Elder, & Co. 1882.

Lectures on Surgery. By JAMES SPENCE, F.R.S.E., Surgeon to the Queen in Scotland, Professor of Surgery in the University of Edinburgh, etc. Third Edition. Two Volumes. Edinburgh: Adam and Charles Black. 1882.

We have placed these books together partly because they happen to have reached a new edition about the same time, and partly because, in spite of some differences, they possess many features

in common. Each is written by a teacher of unusually large experience; each is based on a long course of professorial lectures on systematic surgery, and each is almost exclusively the work of one hand. These characteristics suggest some reflections on the changes that are gradually revolutionizing professional literature.

Whether for good or for evil, the day seems to be rapidly dawning when works like those named at the head of this notice will become extinct. The growth and differentiation of medical and surgical knowledge, the increasing complexity of professional affairs, the continuous evolution of specialties in practice will tend to throw the bulk of medical writings more and more into the hands of experts. Already the shadow of the new order of things is upon us. Systems, dictionaries, and cyclopædias, by many hands, spring up like mushrooms, and threaten to extinguish the old-fashioned treatises framed upon antecedent lectures in which our fathers delighted. The latest development of the innovation has assumed the form of an "International" Cyclopædia of Surgery, owning, it is needless to remark, a transatlantic origin. To all this there is no serious objection, provided the purposes for which these books are compiled are not lost sight of or misunderstood. Works of reference are becoming increasingly necessary in every department of knowledge, and it is essential that the material out of which they are formed should be drawn from trustworthy sources. Accuracy and multiplicity of details are the chief desiderata in a work of reference. But in works intended for primary instruction something else is needed. Lucidity, method, and consistency now become paramount. What Descartes has said of philosophical systems and the various forms of knowledge may be applied to the construction of all educational works. "There is," he says, "seldom so much perfection in works composed of many separate parts, upon which different hands have been employed, as in those completed by a single master"; and, by way of illustration, he adds, "The sciences contained in books (such of them, at least, as are made up of probable reasonings without demonstrations), composed as they are of the opinions of many different individuals massed together, are farther removed from truth than the simple inferences which a man of good sense, using his natural and unprejudiced judgment, draws respecting the matters of his experience." This is especially true of medical writings. A cyclopædia of multiplex origin is usually a heterogeneous mass of detail forming a grotesque and incongruous whole. Some of the articles may possess technical merit, but many are crude collections of isolated facts, and occasionally it happens that two or more articles in the same volume are mutually destructive. On the other hand, a work by a "single master" will not only be free from these defects, but it will exhibit a unity of purpose and a harmony of effect indispensable to the elucidation of fundamental principles and the inculcation of knowledge. For the attainment of these ends the conditions of medical authorship would require to be more strictly imposed. Though there may be many teachers, few possess all the qualifications needed to write a systematic treatise on any branch of medical science. Mere ability will not suffice; the task demands a combination of talents rarely bestowed on one individual. A writer and teacher of the highest rank needs not only an active and cultivated intelligence, but he should in addition possess the instincts of a scientist and the insight of a philosopher. His faculty of observation should be prompt and unerring, his reason clear, his judgment sound; his knowledge of medical litera-

ture, methods, systems, and doctrines should be wide and accurate; and his acquaintance with collateral learning thorough, if not familiar. Doubtless many an author has attained popularity without these qualities; though none, perhaps, has acquired classic fame who did not possess them in some degree. The difficulties are, of course, greater now than formerly. It is not possible for one person to be adept in every department of medical and surgical knowledge; but it is not necessary that a man should be a polymath to be a successful and even a great teacher. Sound knowledge is indispensable, but soundness of knowledge implies depth rather than extent, and consists, as has been well said by the author of the "Intellectual Life," in "the complete possession of its essential parts." The essential parts of every art are the principles underlying it, not all the details of their application. Indeed, the bane of modern education is that soundness is sacrificed to versatility and facts made to assume the place of principle. This suggests the inquiry whether the art, no less than the science, of medicine is not greatly hampered by the circumstances of professional life, and whether each should not have its proper professors. As matters now stand, almost every medical teacher who is not possessed of private fortune has to discharge three distinct and independent duties which are always more or less conflicting and often antagonistic. He has to distribute his time and energies over research, exposition, and practice. The successful performance of one of these tasks often militates against an effectual prosecution of the others. Harvey, the scientist and philosopher, wellnigh ruined Harvey, the medical practitioner. "After his book on the 'circulation of the blood' came out, he fell mightily in his practice; 'twas believed by the vulgar that he was crack-brained and all the physicians were against him." Whether the discoverer of the circulation of the blood was better employed in investigating the mysteries of biology, or exercising himself in "his therapeutic way" by writing prescriptions for which few practitioners would "have given threepence," it is scarcely necessary to ask. The impracticability of attempting to combine the scientist, the philosopher, and physician has been repeatedly demonstrated.

Kant, nearly a century ago, in reference to the necessity of a division of labor, said: "It might deserve to be considered whether pure philosophy in all its parts does not require a man specially devoted to it, and whether it would not be better for the whole business of science if those who, to please the taste of the public, are wont to blend the rational and empirical elements together, mixed in all sorts of proportions unknown to themselves, and who call themselves independent thinkers, giving the name of minute philosophers to those who apply themselves to the rational part only—if these, I say, were warned not to carry on two employments together which differ widely in the treatment they demand, for each of which a special talent is required, and the combination of which in one person only produces bunglers. But I only ask here whether the nature of science does not require that we should always carefully separate the empirical from the rational part."

The duty of the medical practitioner as such, is to diagnose and treat disease, and to employ those means that science has placed within his reach for the prevention, alleviation, or eradication of human suffering. It is no part of his task to attempt the solution of abstruse biological problems. And so he who is fitted by natural tastes, aptitudes, and mental habits to engage in scientific search should not be distracted by the consuming cares

of professional practice or wearied by the tedium of elementary teaching. John Hunter, resentful at the interruption of his dissections by the necessity of earning that "guinea," manifested the genuine spirit of a scientific worker. Between the two extremes of the scientific worker and the practical physician the teacher will find his true place and purpose. He should unite in himself the shrewdness of the practitioner and the enthusiasm of the investigator. While utilizing the labors of both, he should preserve himself from their prejudices. His mission is to expound the doctrines of science, not to bolster up theories whether of his own devising or of another's; and even in teaching medical art he must be neither apologist nor partisan. His privilege is to foster thought in others, and to influence the mind and character of his pupils. This he can only do by keeping his own mind free of degrading prejudices and jealousies. In the words of Locke he "should keep perfect indifference for all opinions; not wish any of them true, or try to make them appear so, but, by being indifferent, receive and embrace them according as evidence, and that alone, gives the attestation of truth." This is impossible as long as success in practice is the goal at which every medical teacher has to aim. Profundity of thought is not to be expected in one who is distracted by the struggles of professional existence, nor judicial impartiality in a competitor for patients. Whether the attractions of teaching will ever supersede those of lucrative practice may be doubtful, but until they do, it is certain that, as heretofore, the greatest teacher will always sooner or later be lost in the fashionable and prosperous practitioner.

We have purposely abstained from comment or criticism of the books before us. They have formerly been noticed more than once in our columns, and it is enough now to remark that the present editions fully maintain the reputation the works have acquired. We have preferred to confine ourselves to a consideration of the conditions out of which they have arisen, and to throw out some hints for the reform of medical teaching and education.

One word in parting. Though Professor Gross's book is the outcome of his college lectures, the several parts have been extended, elaborated, and amplified, till it has become a complete and systematic book of reference alike for the student and the practitioner. The late Professor Spence's work, on the contrary, preserves its original character of university lectures, and as such affords a useful guide to the principles of surgery. A close scrutiny could discover defects, and here and there, perhaps, a few errors, but in its entirety the book is deserving not only of confidence, but of praise. We cannot do better than close this notice with the touching announcement prefixed to the second volume:—"The last line of this volume has been corrected, the last proof returned from the hands of the printer, when death removed its author from our midst; so the end of the work and of the worker have come together. The present edition is therefore in every way the perfect and ripe fruit of his experience."

Essentials of Vaccination. By W. A. HARDAWAY, M. D. Chicago: Jansen, McClurg & Co. 1882.

THIS work professes to deal in a short compass with the whole question of vaccination, and its author has certainly succeeded in his attempt. Beginning with a general history of the subject, it is shown that vaccination was known in many isolated places before 1775, as, for example, amongst

the mountaineers of Mexico; but this fact admittedly in no way detracts from the exact and convincing character of Jenner's discovery. It is taken for granted that there is such a thing as spontaneous vaccinia in the cow, although it is said the disease is rare in America. Several chapters are devoted to such subjects as the history of variola in animals, to the course of vaccinia in the human subject, and some account is given of Reynaud's experiments as to the absorption by the lymphatics of the vaccine virus. Dealing with the question of revaccination, the author insists that the value of the protection afforded is in direct proportion to the thoroughness of the vaccination, and to the quality of the lymph employed; he evidently disregards the notion, which we must admit to be somewhat antiquated, that one revaccination only is necessary in connection with the age of puberty, and he favors its somewhat frequent repetition even when no immediate danger of infection prevails. A large part of the work relates to the respective merits of bovine and humanized lymph, and in connection with the subject of revaccination the author alleges that the virus which has gone through many successive transmissions does lose much of its prophylactic influence. Several authors are quoted as to this, but we cannot forget that the nurses in our small-pox hospitals are revaccinated once only with humanized lymph, and that they retain their immunity from an attack of small-pox notwithstanding.

It is also contended that vaccination with heifer lymph is as easy of accomplishment in equally skilled hands as with humanized lymph, and Dr. Warlomont's success as regards every insertion in 300 children is referred to. This, however, was with fresh lymph; whereas in the case of heifer lymph there must necessarily be a much more frequent resort to preserved lymph than in the case of lymph taken from the arms of children. Besides which, out of 2,727 operations by Dr. Carstan, whose experience is also quoted, success at every insertion was only obtained in 1,563 cases. The remaining 1,164 therefore gave some measure of insertion-failure, a proportion unknown in this country in the hands of skilled vaccinators using humanized lymph. Throughout the volume there is a strong leaning towards the abandonment of what we term arm-to-arm vaccination. Some of the reasons given are sound; certain dangers can be avoided, and some of the objections to the operations are more easily set aside. But the advantages of heifer lymph are, we think, exaggerated. Thus, it is hinted that if the vaccination be performed with such lymph, it is unnecessary to produce the same amount of local effect requisite when humanized lymph is resorted to—an opinion which we believe cannot be supported by any known experience. The questions of insusceptibility to vaccination, of erysipelas following on or due to vaccination, and the inoculation of syphilis, are also dealt with. The views of previous authors, such as Jenner, Marson, Seaton, Buchanan, and others are quoted on the various subjects dealt with, and care has evidently been taken to produce a useful hand-book on the question of vaccination in its several aspects, and especially in its relation to small-pox.

Muscles, Mind, and Morals; or, Hints on the Prolongation of Life. By EDWARD T. TIBBIS, M.D. 12mo. Pp. 94. London: Simpkin, Marshall & Co.

A SENSIBLY written little book, in which the importance of exercise in the maintenance of health is clearly laid down. While fully admitting the

correctness of the author's statements, we would just point out that the difficulty that arises with many men, in the metropolis at least, is the time which would be occupied in faithfully carrying out the plan he prescribes. Throughout many months of the year a walk before breakfast is for a Londoner out of the question; but immediately after breakfast work begins, and most men have to get to their offices as quickly as possible. During the day exercise is impracticable, and we somewhat question whether a two or four mile walk when the system is tired out on an empty stomach, say at five or six o'clock, is very serviceable. Dr. Tibbits would, we have no doubt, say "Why toil so hard? take things more easily." But, alas, time is money, and the work that comes to a man must be got through, well, if possible, but at all events got through. The rest of Dr. Tibbits' remarks are but an expansion of the old adage, "*mens sana in corpore sano*," and he shows in short compass the good influence that exercise duly maintained exerts not only upon the mind but the morals.

Legal Medicine. Part I. By GEORGE MEYMOTT TIDY, M.B., F.C.S. London: Smith, Elder & Co. 1882.

MR. TIDY is following in the wake of fashion, and has given to the world this first instalment of his treatise on Legal Medicine in a very ponderous form. The book is an octavo volume as large as one of the volumes of Ziemssen's Cyclopædia, and weighs nearly five pounds. The paper is thick, the type is large, and the margins are liberal, and to these features chiefly is due the size of the volume. The title-page bears an extract from one of Canon Liddon's sermons, and the volume is dedicated to Baron Huddleston, and thus divinity and law are made to assist as it were at the birth of this last offspring of legal medicine. The book is necessarily, to a great extent, a compilation; and the large number of cases and extracts from medico-legal writers and the medical journals will be found to be among the most useful of the contents of the volume. For the most part it does not differ materially from other works on medical jurisprudence; and the reader who is acquainted with Christison, Taylor, Guy, Ogston, and Orfila will be able to read much of these author's writings in the pages of Mr. Tidy. Certain portions are new, and although their right to be included in a treatise on legal medicine is open to question, they are nevertheless acceptable, for they relate mainly to the chemical part of the subject, and that, we take it, is the part in which Mr. Tidy feels most at home. Then there is an interesting chapter on Combustibles and Explosives, a subject upon which every intelligent man of science will be glad to have some definite knowledge. There is a section on Handwriting and Inks which is interesting, and another on Methods of Embalming, of which the medical jurist ought clearly to have some knowledge. There are twelve chapters in the present volume, which are devoted to Introductory matter, Death, Identity, Causes of Death, Post-mortem Examinations, Sex and Monstrosities, Life Assurance, etc., Heat and Cold, Burns and Scalds, Lightning, Combustibles and Explosives, and Starvation. Thus the present volume deals with but a small portion of medical jurisprudence. The introductory chapter, which was delivered in the form of a lecture at the London Hospital in May, 1881, is less of a compilation than the rest of the volume, and may be looked upon as the digested and matured views of the author. The paragraphs on the "Process of Law" are too meagre, and are deficient in advice as to the mode

of serving subpoenas and the responsibilities they entail, together with details which every medical witness requires to know. The advice is very properly given never to make a post-mortem examination in a hurry or by "artificial light"—although the reason for this latter piece of advice (sound enough in itself) strikes us as peculiar—viz., "*that certain important appearances (such as the yellow color of the skin induced by picric acid poisoning, etc.), might and probably would pass unnoticed.*" "Don't walk down Piccadilly in the dark for fear of not recognizing the Pope" is a parallel piece of advice. It is certainly a very chemical view of pathology.

Coming to the subject of Evidence, we find the following:

"Evidence is of two kinds—(1) *direct or positive*, and (2) *circumstantial*. Thus, if a witness were to say, '*I am certain that the prisoner is the man I saw knock the deceased person down.*' provided the witness is to be believed, such evidence is *positive*, and the jury have no alternative but to find a verdict in accordance with it. But if the witness were to say, '*To the best of my belief the prisoner is the man,*' explaining that at the time the crime was committed the night was dark or that he himself was flurried, then a doubt hangs over the evidence of identity, which at best is merely *circumstantial*."

Mr. Tidy, we hope, means to say that when the direct evidence of identity is defective it will have to be established by circumstances; but he is not clear, and the student would be apt (if he were a very foolish and ignorant one) to take Mr. Tidy's last sentence in italics as a sample of circumstantial evidence.

Again, when speaking of the differences between common and skilled witnesses, Mr. Tidy says: "*A common witness has to speak to the matters of fact which have come within his personal knowledge—that strychnia was present in the stomach of the deceased,*" etc. It is something new to be taught that the presence of strychnia can be sworn to as a fact without the evidence of a skilled expert. A common witness might say that he saw some white powder in the stomach, or that what came from the stomach was bitter; but no common witness is capable of swearing to the presence of strychnia in the stomach, and we think that those whose profession it is to do so would object to be paid the fee of a common witness for this trouble.

Next we come to this remarkable paragraph:—

"And here a few words are suggested on the vexed question of *expert evidence*. Nothing is more terrible to contemplate than a traffic in evidence either for gain or notoriety. Hence we lay down this definite rule, that, in our judgment, should always guide the scientific expert—viz., that no one is justified in giving evidence in support of a case, or in support of that part of a case upon which he may be specially retained to give evidence, that he does not believe to be right and true. Any evidence offered by the expert in the witness-box should be as honestly and truly his scientific belief, influenced by reasons as definite and as accurate, as if he were arguing the points in dispute before a scientific tribunal competent to weigh his arguments and pronounce on his opinions with accuracy and precision."

It is rather galling to be advised in this quiet way that on the whole you had better be honest.

The paragraph is terribly suggestive of the nature of science in a law court, and seems to give color to the degrees of comparison of untrustworthy evidence once given by a now well-known judge—viz., "*positive, lies,*" "*comparative, big lies,*" "*superlative, scientific evidence.*" We hope Mr. Tidy will omit this paragraph in his next

edition, and substitute for it a shorter one, to the effect that a scientific witness is expected to speak "the truth, the whole truth, and nothing but the truth."

Brain. January, 1883. The original articles in the current number of this journal comprehend several which are of considerable interest. The first is an excursus into the region of pure hypothesis regarding the possible origin of the systemic diseases of the spinal cord from functional disturbance, by Dr. H. Donkin. An account of some interesting observations on the characters of the loss of hearing in hysterical hemianæsthesia is contributed by Dr. Walton, of Boston, U.S.A., the observation having been made in Charcot's wards. Dr. Ross, of Manchester, continues some clinical observations on the spasmodic paralysis of infancy. The theoretical pathology of angina pectoris and its bearing on the phenomena of counter-irritation, are discussed by Dr. Allen Sturge; and Dr. Ferrier describes a curious case of hemiplegic muscular atrophy. The shortest paper is perhaps the most valuable—a very careful collection of statistics on the subject of chorea by Dr. Angel Money.

Medical Annotations.

"Ne quid nimis."

TRUE KNOTS OF THE UMBILICAL CORD.

In the report of the Lying-in Hospital of Munich, published in the last number of the *Archiv für Gynæcologie*, Professor von Hecker gives the results of his observations on knots of the umbilical cord. This state of the cord was met with 83 times in 20,515 deliveries, or once in 247 labours. These knots are brought about by the passage of the child through a loop of the cord so placed that its foetal lies under the placental end; otherwise the passage of the child through it would only cause its disappearance. They may be produced during pregnancy or during labour; in the vast majority they arise during labour. These are readily recognized; they are loose and easily undone, and when undone leave no marks on the cord; while knots formed during pregnancy give rise to atrophy of the cord at their seat. It might be expected that a large and capacious uterus would at least favor, if it were not necessary for, the occurrence of the changes in the position of the foetus and cord which take place in the production of knots; but Hecker found such was not the case. Of the 83 cases, 32 were primiparæ and 51 multiparæ; this proportion is much the same as the proportion of total primiparæ to the total of multiparæ forming the 20,515 cases delivered. Of the multiparæ, again, 23 were two-para, 16 three-para, and 8 four-para, while only four women had had more than three children previously. Moreover, in only four cases was an unusually large quantity of amniotic fluid observed; while in three cases of twin pregnancies, two them being primiparæ, knots were present. These facts appear to show that the conditions necessary to the formation of the knots are not those which favor the mobility of the child, but that their production is essentially dependent on the position of the loops of the cord during labour. In 76 of the cases the vertex presented; in 77 delivery was accomplished by the natural efforts; in 73 labour set in at full term, in nine at nearly full term, and in one at the fifth month. With regard to the effects of the knots on the child, it was found that 69 of the children were

born alive; five were asphyxiated but afterwards restored, four were dead before labour, three died during labour, and two were asphyxiated and not restored. This gives a considerable mortality—11 per cent.; but it does not appear to depend upon the presence of the knots, for in all the cases, with two exceptions, other conditions were present which were sufficient to cause death. Again, in all the cases but four the length of the cord was above the average, and the mean length of this structure was 71.54 cm., or 21.54 cm. above the normal average. In several of the cases the placenta was attached to the lower part of the uterus. The position of the rupture in the bag of membranes showed this. This condition was noticed in 39 of the cases, and in 13 only was the tear central, while it was lateral in 20 and marginal in 6. The position of the knot was observed in 50 cases; in 41 it was near the navel of the child, and in 9 only near the placenta. In one case two knots were present, and in one case the knot was doubled. These observations are not only of great interest, but they are also of much value in their bearing upon the results brought about by knotting of the cord. Their apparent harmlessness probably depends upon the great length of the cord permitting movements of the foetus and its escape from the uterus without occasioning tightening of the knot. Indeed, knotting of the structure appears impossible—at least towards the end of pregnancy—in those cases where the cord is short, for a certain length is necessary for the formation of a loop which would permit the passage of the child through it. It is not improbable, moreover, that the lesions which have been described as the results of loops or knots of the cord, have occurred in cases in which the cord was comparatively short, but yet of sufficient length to permit the formation of loops or knots, but not of such length as to permit, without tightening, free movements of the child.

HURRY, WORRY, AND WASTE.

ATTENTION is every now and again called to the many irresistible proofs which exist that there is something radically wrong in our modern mode of working, and rarely a week passes without some signal collapse in the ranks of our foremost men. An endeavor has been made to show that the cause of that brain-wreckage which so commonly occurs among statesmen and politicians is the bad habit of turning night into day, which has been formed by the British Legislature. The truth is, however, that the breakdown of public men is not due to any special cause. They are affected, as the ordinary members of modern communities are affected, by the hurry, worry, and waste that are characteristics of the age in which we live, and which pervade all classes and sections of the community. The demon "over-work"—erroneously so called—is as active among commercial men who go to bed at ten or eleven o'clock as amongst statesmen who sit up hearing and making speeches until the small hours. Side by side with this fact must also be set another—namely, that as a rule the votaries of fashion and gaiety sit up a good deal later than members of Parliament, and yet do not suffer half so much. In truth we must look below the surface if we would search into the deep effective cause of the troubles we lament. It is not "over-work," but worry, that kills. Our men of brain might do a great deal more than they do if only they were less feverish in their haste, less harassed by worry, and less wasteful of energy. We are all too much in a hurry about what we do. We have too many irons in the fire, too much business on hand at the same instant, and are far too

energetic in our endeavors. With deliberation, calmness, and such reserve of strength as result from perfect restraint, a man may do an infinity of work without either trouble or injury. Breathless haste, eager anxiety, and an excessive expenditure of energy are the outcome of modern activity, whether in this country or on the Continent. The system of "quick returns" has been the bane of literature, almost distinguishing it and substituting in its place "journalism." The same system has revolutionized thought and science, and it is rapidly undermining the human constitution. We are impatient for results. Speeches are made with the knowledge that they will appear in print in a few hours, and that if anything is omitted the deficiency will be criticised by some watchful opponent in the Press. Every opportunity must be seized as it presents itself, or it will be lost. It follows that statesmen and politicians are kept on the strain of sustained attention, and their brains are for many hours in the twenty-four, whether in or out of Parliament, in a condition of ferment. The brains of speculators on the Stock Exchange, and even the brains of merchants in their private rooms, are equally taxed, and in the same way. All classes of the community share the turmoil. The period is one of brain-wearing impetuosity, of hurry, worry, and waste—the waste of cerebral energy and nerve force. The higher nervous centres are kept incessantly at work, and become, as it were, overheated, so that it is impossible they should quiet or cool down in the brief intervals of respite allotted to repose. Too often they do not rest even in sleep. The brain only dozes instead of sleeps, and as a result there are dreams of the recent day's work, that infallible symptom of impending mischief. The only marvel is that, looking to the utterly unphysiological character of our mental and nervous habits of work, the number of sudden failures is not greater than it is, and that we have not a larger percentage of brain-mortality to deplore.

ADVERTISING IN THE LAY PRESS.

ALTHOUGH the resolution passed last summer by the Royal College of Physicians condemning the practice of extensively advertising medical works and giving laudatory certificates with regard to medicinal and other preparations has been followed by very manifest results, it has not succeeded in entirely checking the practice; instances of which, when they do occur, attracting even more attention because of their being happily less frequent than formerly. A very marked contravention of the resolution of the College appeared in *The Times* of February 1st, in the form of an advertisement of one book occupying three-quarters of a column; surely an "extensive" advertisement in the most literal sense. It consisted of a number of separate lines setting forth the title of the work some twenty separate times, and after each enumeration of the title the name and qualifications of each contributor to the volume. It wanted only the indication of the subjects upon which these gentlemen respectively wrote to render it complete. We do not for a moment imagine that a single one of them has approved of the liberty that has been taken with his name; but we believe that they would one and all repudiate the act which brings them so prominently before the public, their names and titles being paraded in a column flanked on either side by notices of patent medicines. It is, moreover, difficult to see what gain can be derived by such a system of advertising, even for trade purposes, that could at all compensate for the distress and annoyance that must be caused by it; and we question the right of publishers, however

influential, to thus traffic with the names of contributors without their consent. To the profession, it is needless to point out that the very excellence of the work and the high character of its authors (including the President of the College of Physicians himself) render such advertising harmful in the highest degree, for it appears to give countenance to a practice which some authors would, it is to be feared, be only too pleased to adopt, especially as they would seem thereby to be following an example set them in high quarters.

FILARIA DISEASE.

DR. PATRICK MANSON contributes to the twenty-third issue of the *Chinese Customs Medical Reports* some further "Notes on Filaria Disease," with especial reference to filarial periodicity, the fate of the embryo parasites, the intimate pathology of the disease, and the causation of abscess by the death of the parent worm. He confirms the results of Dr. S. Mackenzie's experiments with regard to the inversion of the hours of sleep and waking, and adopts Dr. Mortimer-Granville's view that it is not simply the inversion of these states that exercises the influence on the filarial periodicity, but that "it is something recurring every twenty-four hours, just as the habits of sleeping and waking recur, and which is capable of being inverted just as these habits are, and by the same means." What this *something* may be is not yet clear, but it will be remembered that the ingress of the embryos commences some hours before the usual time for sleeping, and the egress similarly before the usual time for waking. From further experiments, which Dr. Manson hopes to make more complete hereafter, he thinks that filarial periodicity is maintained during prolonged watching, and also when the hours of the middle meal are changed from midday to midnight; also that prolonged sleep probably disturbs periodicity in the direction of diminishing the number of parasites in the circulation at the maximum period, and similarly when the usual eight hours' spell of sleep is broken up, and during an attack of fever. Dr. Manson cannot confirm Dr. Myers in his supposition that the filariæ die daily, and in the sequence that filarial periodicity depends on intermittent reproduction, and that we have to deal with a fresh swarm every twenty-four hours. He adheres to the view, illustrated apparently by the analogy of *F. immitis* in the dog, that the filariæ retire daily for a time to some organ or set of vessels. He believes "that filariæ embryos are nearly constantly passed into the lymph stream, and that whenever lymph finds its way into the urine, no matter at what hour, nor how long it has been running, it contains the parasite." The act of parturition is therefore a continuous process, and a test-case is recorded where filariæ were constantly found in urine rendered chylous by the rupture of a lymphatic in the urinary tract. Dr. Manson is confirmed in this view because his experience is that the filariæ are usually tenacious of life outside the body, and live on the slide as long as the blood-serum remains fluid or viscid. The languor observed by Dr. Myers may not be preliminary to disintegration, but to a periodical state of rest. Moreover, he has never seen in freshly drawn blood dead filariæ other than can be accounted for by violence. With regard to the intimate pathology of the disease, it is recognized that the parent worms and their offspring do not always, or even generally, give rise to disease in their host; and Dr. Manson believes that elephantoid disease, when it occurs, is due to the miscarriage of ova. He found on one occasion on puncturing an enlarged groin some ova (C. M. R.,

xviii., 49), and he then concluded that the parasite was oviparous, but subsequent examination of two specimens of the mature worm convinced him that it was viviparous. After a fruitless search for ova on many other occasions, a second case turned up in which ova were found in the lymph from a scrotum. Now the parent worm (as far as present knowledge goes) lies on the distal side of the glands, and this is probably her normal habitat, consequently her long, sinuous, powerful progeny (1-3,000" diameter) travel through the glands to reach the thoracic duct and blood-current. The miscarriage or premature expulsion of ova, however, is easy considering the method of expulsion, and the vast number of the progeny, but these ova (1-750" to 1-500") cannot pass the glands, and they plug the lymph-channels one after another, first in one part and then in another, where the current seeks to re-establish itself, until the entire lymphatic system is blocked of the part connected directly or indirectly with the vessel in which the parent worm is lodged. Abscess of the thigh and scrotum in China is frequently produced, Dr. Manson thinks, by the death of the parent worm, and he figures from such a source the fragment of a dead mature worm with embryos, and one ovum escaping from the uterus. With this exception all other phases of elephantoid disease are, he believes, produced as we have explained above.

DR. VAN BUREN.

We regret to learn that Dr. Van Buren, of New York, continues seriously ill, and that he has been compelled to resign the chair of Surgery at the Bellevue Hospital Medical School, which he has held with great advantage to the school and distinction to himself. Dr. Van Buren is best known in this country as the joint author with Dr. Keyes of a work on the Surgical Diseases of the Genito-urinary Organs. We believe there will be several candidates for the chair he vacates.

THE ANATOMICAL SOCIETY OF PARIS.

THE oldest established of the Paris medical societies, and one which has contributed so much to the study of morbid anatomy, is the Société Anatomique, to which M. Cornil has just been elected president in succession to M. Charcot. In his few opening remarks M. Cornil adverted to the history of the Society, the work it has done, and that which it has to do. He reminded his hearers that the Society was founded at the commencement of the century under the auspices of Dupuytren and Laennec; that after an interval of ten years' silence it was reconstituted in 1827, when Cruveilhier was elected perpetual president. In 1875 M. Charcot succeeded to the chair, which he has now yielded to M. Cornil. The Society is the field where most of the young internes earn their laurels; and its Transactions are a rich storehouse of pathological facts.

DR. OLIVER WENDELL HOLMES.

DR. WENDELL HOLMES has been appointed Emeritus Professor of Anatomy to Harvard University, and the report of the Committee of the Board of Bursars recommending this nomination refers to the fact that for more than thirty-five years Dr. Holmes had filled the chair of anatomy. "Taking great interest in his classes, he has met them with conscientious punctuality and never-failing enthusiasm. By the ingenuity of his demonstrations, the vividness of his descriptions, the brilliancy of his imagination, and the ever

ready resources of his varied condition, he has given to the dry details of a difficult study a rare attraction; each lecture, prepared with exact fidelity, being delivered with all the freshness of a first occasion." The report goes on to refer to his services in the cause of medical education, sanitary reform, charities, and public improvements, and says "he has hastened the advance of rational medicine. He argued the practice of what is now technically called 'surgical cleanliness' before Listerism was broached. His writings add dignity to the profession of medicine, increase respect for the honorable and educated physician, and discourage the charlatan." His retirement from the university, the committee point out, "calls for the expression of profound regret, and for the fullest academic recognition of his long and zealous devotion to its interests."

BACTERIA.

It is well known that bacteria are widely distributed and find entrance into the living organism in health as well as in disease. M. G. Colin recently communicated to the Académie des Sciences a memoir on this subject, in which he arrives at the following conclusions:—There is no part of the respiratory and digestive apparatus in which bacteria are absent, under normal circumstances, and in some localities they are met with in enormous quantities. But normally all these bacterial liquids are inoffensive. The microscopical organisms confer no virulent or toxic property. The liquids only become dangerous after some degree of putrefaction, and their effect is the same for all: the production of septicæmia. The microbia and their germs, which are found in the respiratory or digestive tracts, are probably, in the living animal, carried into many localities by diffusion-currents, and certainly in the dead body they reach all parts, and develop there if they meet with favorable conditions.

PORRO'S OPERATION IN ITALY.

DR. BIANCHI reports (*Gazzetta degli Ospitali*, Jan. 24th, 1883) a case in which Dr. Barsotti performed Porro's operation, at Lucca, on Dec. 28th, 1882. The patient was rickety, and suffered from pneumonia and mitral insufficiency. The deformity of the pelvis was so great as to render any process of embryotomy impossible. The operation for the removal of the uterus and ovaries presented no unusual difficulty, but the mother died from exhaustion the following day. The child (male) survived, and was in good health at the end of a fortnight. According to Dr. Negri, Porro's operation was performed in Italy thirty-eight times from May, 1876, to May, 1882; fourteen of the women recovered and twenty-four died. It would also be interesting to know how many of the children survived.

THE TREATMENT OF INFLAMMATION.

THE diapedesis of white corpuscles which occurs in inflammation is produced, according to Cohnheim and Hering, as a sort of mechanical filtration through the wall, but, according to Binz and others, is a vital process intimately connected with the irritability and chemical integrity of those structures. The opinion held as to the nature of the process must, as Binz has lately pointed out, modify considerably the therapeutic method employed. If there is only a mechanical extrusion of the cells through the wall of the vessel, it is of paramount importance, in all internal inflammations, to lessen the blood pressure. If, on the

other hand, there is an independent exit of the corpuscles which adhere to the wall of the dilated vessels, the aim of therapeutic measures must be to lessen their activity. Binz asserts that the white corpuscles only escape when the red corpuscles are passing by the stationary pale ones, and only so long as the latter possess the power of adhering to the wall, and the passage seems to be attended by changes of form similar to those which are presented by the corpuscles outside the vessels. He states that the diapedesis is stopped if the vessel is tied, and it is stopped also on both sides of the ligature, and therefore where the blood pressure is completely arrested as well as where it is in full force. It also stops when the colorless cells are paralyzed by any agent, such as quinine, eucalyptol, iodoform, or salicylic acid, without the heart or the vessels presenting the slightest alteration.

THE CHOLERA IN MEXICO.

No little apprehension is felt at San Francisco lest the cholera, which recently made its appearance at Chiappa, in Mexico, and has since extended northwards, should reach California. The districts which have been invaded by the epidemic are so near the forts of Guatemala and of Central America that there is considerable danger of its being brought to San Francisco and other ports of the Pacific by trading vessels. The cholera broke out at San Francisco in 1849, having been brought by a convoy of emigrants who had come across the plains from the Atlantic coast. The outbreak was soon got under then, but some of the poorer districts of the city are now so unhealthy that the result of a fresh epidemic might be much more serious. It is further to be noted that Chiappa, where the cholera first made its appearance in Mexico, is in the same latitude as the English West Indian possessions, where the cholera generally manifest itself first; so that it would be really interesting to ascertain whether the epidemic originates in the tropics of the Western hemisphere. One or two New York journals suggest that a competent medical man should be dispatched by the National Board of Health to Mexico in order to study the march of the epidemic.

MONGREL WORDS.

AMONG the duties of the Registrar-General might, with some profit, be included that of recording the birth of mongrel or misbegotten words with which medical literature is more and more inundated. Although no department is free from this terrible invasion, it is to gynaecology that we turn as the field where these creatures wanton and are rampant. They remind us of the strange exhibitions to be seen at country fairs for the sum of one penny—such as the pig-faced lady. But we will not compare them to the mermaid, round whom time has thrown something of a halo of romance; to the wyvern or the gryphon, the props of so many ancient houses; nor to the chimera of classical memory—so ugly, so unromantic, so unnecessarily and atrociously hideous are they. It is perhaps too late to protest against "cellulitis," or possibly "vaginitis," or "retro-uterine;" but why should we be obliged even to recognize the existence of such words as "peri-uterine," "pericerebritis," "endo-cervicitis" (a sort of sandwich nastier than any ever purveyed at Mugford Junction), or the wanton insult of "atrophicans" or "amyotrophic"? To tell the truth, most of these monsters are not of British breeding, but are generally imported from abroad, and in this respect we are doubtful whether the stolid unscrupulous-

ness of a German or the gay indifference of a Frenchman produces the more excruciating results. If these words are mostly coined abroad, they are adopted without scruple here; it is sufficient for many (who ought to know better) that a disease has been called the — of Prof. Geheimrath von Wurst, or the — of M. le Docteur Le Gros, for them to embody it and do their best to propagate it, instead of resolutely refusing it admission, or at least holding it up to proper derision in inverted commas, if it has unfortunately already taken root. We learned at school, "*Ingenuas didicisse fideliter artes emollit mores, nec sinit esse feros*;" but these gentlemen seem to think that the fact of such words being "*fera natura*" is sufficient excuse for "preserving" them. It does not, however, follow that a German professor who makes interesting autopsies is necessarily skilled in philology, any more than it follows that a Lord Chief Justice is necessarily an authority on experimental physiology, or a president of the Obstetrical Society on counterpoint and fugue. Besides, there is something ungenerous in the whole concern. The ancient Greeks are dead, alas! the ancient Romans are also no more (we wish we could say "*Alas!*"), and cannot defend themselves. If these gentlemen must try experiments, let them do it on each other; let the Frenchman make words with English heads and German tails, etc., and see how they all like it. It seems to us far from improbable (though we are not able to state it as a fact) that Dr. Schliemann's recent excavations have been materially facilitated by the commotion which such liberties must have produced among the bones of the Trojan heroes. The mode of production is probably very simple: you borrow a Greek and a Latin dictionary from a friend, look out one or more words, prefixes, and terminations from each, and put them into a sort of literary rat-pit to fight it out together. Seriously, these words are rarely necessary; they are mostly new names for things which have been known since the year 1; but if a new name should become necessary, its formation is too important a matter to be dealt with in this way. For the offenders—in Latin at least better than their own, however far removed from a classical type—we would suggest the following prescription:

Herr Geheimrath Prof von Wurst.

R Felem novemcaudatam (3×3).

Dorso vel natibus ter die fortiter applicandam.

SPINA BIFIDA.

A SUB-COMMITTEE of the Clinical Society of London was appointed a short time ago to investigate the treatment of spina bifida by injection. We gladly accede to the request of the committee to state that they are anxious to receive: (1) Reports of cases treated by this method; (2) descriptions of specimens of this deformity; (3) recent preparations, or examples in still-born infants, which they may be allowed to dissect; they suggest that these specimens when dissected should, if not otherwise desired by their owners, be presented to the Hunterian Museum. The committee will also be glad of the opportunity of examining living examples of this deformity. Letters should be addressed to Mr. R. W. Parker, 8 Old Cavendish-street, and specimens forwarded under cover to Mr. F. S. Eve at the Royal College of Surgeons, Lincoln's-inn-fields. We gather from this request that the committee intend to investigate not merely the actual statistical results of the injection treatment of spina bifida; by a careful study of many cases and specimens it is to be hoped that they will be able to determine such facts about the natural history of spina bifida as

will form a rational scientific guide to its treatment. We trust that the committee's appeal for aid will be responded to by all who can give them information.

THE PHYSIOLOGY OF THE CRINOLETTE.

A CRITICISM of the details of male and female attire comes legitimately within the scope of medical practice, and at a time like the present, when so much attention is being paid to what is vaguely known as "hygienic dress," that criticism may not be out of place. The most recent fashion in female dress is prominently characterized by the "crinolette," a structure of cunning and mysterious workmanship, with the outward and visible signs of which we are being rendered very familiar. The crinolette is to the crinoline what varioloid is to small-pox—a mild and modified form of a serious affection. The æsthetic value of this strange garment and its significance as a means of decoration we do not propose to discuss, although if it be true that "dress is to the body what language is to thought," it would be interesting to ascertain what this deforming protuberance is intended to express. We can look at it only with physiological eyes, and even from such a limited point of view the garment is interesting enough. In the first place this conspicuous appendage is heavy; its skeleton is, we believe, of steel, and its soft parts of horsehair; and it must add not inconsiderably to the burden to be already borne by the fashionably dressed female. It would not, perhaps, be difficult to demonstrate the exact amount of unnecessary waste of muscular force that the wearing of the excrescence involves. Not only, be it noted, has the sheer weight to be carried, but there must be a good deal of fine muscular action required to adjust the body when erect to this slight but certain disturber of its line of gravity. In the next place, the crinolette offers a distinct impediment to the act of walking, and in this way again involves considerable muscular activity. As a feature in out-door clothing, therefore, it appears singularly inappropriate. Moreover, it is very desirable that the body should be as evenly clad as possible, and that its temperature should be maintained in all parts at one uniform level. The crinolette very grossly disturbs this principle, and by keeping a mass of unnecessary clothing over one part of the body, throws an undesirable strain upon the heat-regulating properties of the skin. This garment, moreover, is secured round the waist, adding one more constriction to that part, one more burden to be borne about it, and making one more addition to its already too numerous coverings. Lastly, the crinolette even now bids fair to compete with the crinoline in encouraging a prevalence of "deaths from fire."

AN ENGINEER'S LUGGAGE.

THE almost motherly care exercised by the Government, and others in authority over us, respecting our lives and welfare, which is so often held up to ridicule, is fully justified if we may judge by one instance of the extreme recklessness and utter disregard of human life and property displayed by some members of the community. An engineer, of Newcastle-on-Tyne, was on January 15th fined £20—a most inadequate penalty—for carrying, in conjunction with his assistant, a large quantity of blasting gelatine, which was to be used to blow up a dangerous wreck at Deal, in a second-class *smoking* carriage on the North-Eastern Railway. The explosive compound was carried in hand-bags, and it is painful to imagine the probable result of an accidental kick by a

blundering passenger, or, supposing these bags to have been placed on the network above the seats, a sudden jerk of the train in starting or stopping which might have sufficed to dislodge them. A glowing fusee or the smouldering end of a cigar might have fired a charge that would have annihilated passengers and train, and would have effected in a moment such widespread destruction as fogs, deficiency in the working of signals and block system, or any of the numerous causes which usually contribute to our railway catastrophes, would not bring about in a decade.

SUICIDE BY CHILDREN.

THERE is, unhappily, no room to doubt that children—especially precocious children such as the social system of France produces—resort to suicide in a startling proportion of instances without being insane in any scientific or practical sense. Probably no other community sets the same value on life which we are accustomed to attach to it. It is the possession we most prize, and that with which we are least likely to part as an act of free-will. Except under extreme pressure no man or woman in this population voluntarily dies unless life is utterly unbearable. It is otherwise with peoples accustomed to see life thrown away under very slight provocation, and who generally regard it as something which has a market value not above price. With such habits of thought and expression as prevail in society on the Continent, children of even tender years are likely to fall into heroic states of mind and perpetrate acts which end in their deaths, without actually appreciating what they do. These young persons are not mad or deranged, or even particularly emotional; they are simply the victims of bad example and vicious influences. There is practically no family life in France, and there never can be so long as the individual, instead of the family, is regarded as the unit of the nation. We are drifting into the same economic fallacy in England, and when the idea is popularized, so that the orderly constitution of society is destroyed, as it is on the other side of the silver streak, we too shall be discredited by the prevalence of suicides among the young. The state of matters in this respect which exists in France is a disgrace to that nationality. The question is not one of medical science, but of political economy.

RADICAL CURE OF PROLAPSUS UTERI.

Dr. CANEVA, of the Ospedale Maggiore at Milan, comments, in the *Gazzetta degli Ospitali* of Dec. 20th, 1882, on the unsatisfactory results of mechanical supports, and of vaginal plastic operations, in the treatment of complete uterine prolapsus. He recommends an alternative operation, with the object of suspending the womb from above, by promoting adhesions between its body and the parietal peritoneum in the hypogastric region. The patient is to be kept in bed for some days before the operation, to maintain the uterus reduced. The bowel having been cleared by injection the previous evening, and the bladder emptied just before anæsthetization, whilst the patient is lying on her back, the operator introduces a metallic sound, and entrusts it to a competent assistant, with instructions to maintain the anterior surface of the uterus in contact with the abdominal wall. Commencing at a point two inches from the pubis, an incision is to be made three inches upwards along the linea alba down to the peritoneum over the body of the womb, which can be felt by the finger with increasing distinctness as the division of successive layers proceeds. So soon as the peritoneum is reached, the

most delicate stage of the operation is entered upon. The wound is to be enlarged transversely, and an area of peritoneum at least an inch and a half in diameter exposed, by drawing aside the margins of the wound and detaching the serous membrane with the handle of the bistoury or with the finger. The assistant holding the womb fixed with the sound against the exposed peritoneum, the operator, with a fine needle threaded with catgut, sutures the parietal peritoneum to the corresponding serous investment of the womb. The sound is not to be withdrawn, until the surgeon has satisfied himself that the proceeding has resulted in the effectual suspension of the uterus to the abdominal wall. In closing the wound, two or three of the stitches are to include the peritoneum. The whole procedure is to be conducted with strict antiseptic precautions and Listerian dressings. Dr. Caneva has not given any clinical results, but promises a further contribution.

Correspondence.

"Audi alteram partem."

"INUNCTION IN SCARLATINA."

To the Editor of THE LANCET.

SIR—As this subject is one of considerable importance, kindly allow me to add a few words to the discussion. Inunction has done some good service, and should not be hastily condemned as a dangerous and perilous proceeding. No better means exist for isolating successfully scarlet fever cases among the crowded houses of the poor. It is easily applied, and its efficacy to prevent the spread of infection is believed in by the people who use it. I would be very sorry to disturb a growing popular faith which is so useful, unless there were sound reasons for doing so.

The objections that are brought against inunction are that it clogs the pores of the skin, and so checks perspiration, thus throwing the function of the skin on to the kidneys, and disposes to the sequelæ of albuminuria, dropsy, and rheumatism. If this is true, then inunction ought to be abandoned, and some of the other more cumbersome modes of daily disinfecting to be substituted. The objections seem to me to be based on the idea that inunction is just the same as varnishing the whole body or immersing it in oil. If inunction were in any way similar, I would at once admit the seriousness of the objections; but it is fortunately very different. The skin requires a certain amount of oily matter, otherwise sebaceous glands would not be placed all over the body excepting the palms of the hands and soles of the feet. In the febrile state the epithelium gets hard and dry, and the secretions of the skin are arrested. The rubbing in of oil makes the harsh epithelium soft and supple, and encourages perspiration instead of further checking it. This lubrication also lowers an elevated temperature, as I have on several occasions tested. If of benefit in the febrile stage of scarlet fever, it certainly can do no harm during the desquamative stage, but rather good, as the patients seem less liable to take cold; while it is of inestimable value in arresting the most pregnant source of infection, the shedding and scattering of the minute epithelial scales.

With this object I have for the last fifteen years used the oil in many serious epidemics of scarlet fever, and have been surprised at the rarity of albuminuria and dropsy where inunction has been used; while these sequelæ were common enough

among those who did not use it. During the last two months I have had forty cases of scarlet fever in my district. Carbolized oil (1 to 30) was distributed. Two cases of dropsy occurred. On inquiry I found that in neither of these cases had the inunction been used.

The rubbing of oil into the skin cannot be so very dangerous, or it would not be so general a custom in eastern countries. It is the only toilet of some African nations, keeping the skin soft and its functions active under a scorching sun and in a hot, dry atmosphere. The ancient athletes oiled their bodies before entering on their contests, and Celsus recommends old oil to be applied with friction in fevers.

With this old and general use of inunction we never read or hear that anasarca was a usual accompaniment, as it ought to be if the theories of the objectors to inunction were the result of practical experience.

I am, Sir, yours very faithfully,
J. SINCLAIR HOLDEN, M. D.

Sudbury, Suffolk, Dec. 4th, 1882.

THE ANTEGENETIC DISCOVERY OF FŒTAL SEX.

To the Editor of THE LANCET.

SIR—Medical scientists have hitherto greatly relied upon the ascertained rate of pulsation of foetal hearts as a means of an antegenetic discovery of the sex of the child. (The term antegenetic conveniently embodies the idea "before birth," and is homologous with the word antenatal.) But the method is admittedly unreliable, even to the most accomplished ear; and the object of observation itself gives rise to so many fallacies that any conclusion drawn from it must be, to a great extent, conjectural.

There is, however, a common expression as to the manner of "carrying" the child—the external appearance during gestation—which has not received the attention which I believe it deserves. Simply stated, the form of the abdomen is a great means of diagnosing the foetal sex, and is, after a little training of the eye on the point, less open to fallacy, though *ex facie* more so than the counting of the cardiac pulsations. Briefly formulated, if the form of the abdomen be conoid and projecting (child carried in front), the child is male; if the form be more flattened and rounded (child carried round about), the child is female. The manner of gestation must be observed personally; no statement of the patient is to be absolutely relied upon. Absolute size of abdomen I do not now notice to have much bearing on the question, save as a guard against occasional cases of plural birth.

These principles have been put to a practical test in the course of the last twelve cases of labour which I have attended, and with the following results:—In two I could make no prediction, owing to the children having entered the world almost simultaneously with my entering the room; in a third (which I delivered for a midwife with the indicating axis-traction forceps, it was a matter of greater concern to see the sex of the child than to predict it, especially as the conditions for prediction were unfavorable. The remaining cases were those of eight multiparæ and one primipara, who gave birth to seven male and two female children, all cases of single pregnancy it will be seen, and all were head presentations. As to time, one was three weeks, another four days before, and the remainder in the course of the first stage of labour. Position and dress have, in most cases, no great influence on the result. I have reason to

believe the method applicable to breech presentations, and to a period of at least two months before delivery. I positively diagnosed the sex of seven of the nine, but was more guarded in the cases of two of the multiparæ, to whom I "expressed the opinion" that the children would prove to be males. They were males, so that I was correct in all the cases where there was any ground for judgment. My reasons for less confidence in the two cases mentioned were, in the one, an habitually small parturient projection, but the patient remarked that "she carried this one more in front than the last," which was a girl; and in the other a rather indefinite conoid shape, due to abdominal obesity, which is a source of occasional indetermination. In the latter case the fetal heart was 144 in the interval of a pain; in the former I did not auscultate.

As yet I have not even constructed an hypothesis to explain the facts, but further clinical observation may give rise at least to a theory. And this observation may be very well made and recorded by using a strip of pliable metal, such as lead, for the purpose of obtaining an outline of the abdomen in the plane passing through the spinous process of the second lumbar vertebra and umbilicus, and a tracing of the abdominal curve between the xiphoid cartilage and the pubis.

I am, Sir, yours sincerely,

A. DRUMMOND MACDONALD, M.B. Ed.

Peel-street, Dingle, Liverpool, Jan., 1883.

NEW YORK.

(From our Correspondent.)

THE year closes with the publication of some excellent works on Histology and Anatomy by the American publishing houses. I will briefly refer to some of them to which my attention has been drawn, and as my task is descriptive and not critical, I will leave any expression of opinion as to the merits of the works to the authorized reviewer.

Messrs. J. W. Vail & Co., New York, publish a work on "Microscopical Morphology of the Animal Body in Health and Disease," by Dr. C. Heitzmann. This is a handsome volume of about 850 pages and illustrated in a manner that leaves no room for improvement, with 380 original engravings made from drawings by the hand of Dr. Heitzmann. As Dr. Heitzmann is a skilled professional microscopist and an excellent draughtsman, the work must be esteemed a valuable one, if only as a record of histological work, which the author claims to have occupied ten years of intense labor. Had Dr. Heitzmann merely recorded the result of his microscopical observations, the work would doubtless have been received as an authority on the subject and proved highly acceptable to students following this line of research. But Dr. Heitzmann has assumed the rôle of a reformer, and aims to overthrow the cell theory and modern views on protoplasm and living matter, presenting in their place original theories of his own, and urging on the reader facts and conclusions which he is not sanguine will meet the approval of professional microscopists. The whole work is based on the assertion that protoplasm consists of a number of granular bodies from which radiate delicate greyish threads, the ends of which blend with other granules, so as to convey the idea of an extremely delicate network, the outer contour (an amoeba, quoted as an example), consisting of a continuous thin layer of a slightly shining substance, into which also penetrate filaments from the granules. Dr. Heitzmann observes this struc-

ture in the amoeba, the red and white blood-corpuscles, and in all forms of protoplasm and living matter. This reticular structure in the hands of Dr. Heitzmann enables him to explain the phenomena of the development of living matter, and many of the mysteries of organized life. He appears to have established in this city a school of microscopists who are devout believers in his theories, while the larger number of histologists give Dr. Heitzmann's conclusions a cold reception and exhibit a want of faith which must be distressing to one imbued with so much enthusiasm. Dr. Heitzmann's book includes papers by about twenty microscopists, who may be termed his disciples; many of these show undoubted talent, and are valuable contributions to the literature of the subjects treated. Dr. Heitzmann labors under the difficulty of writing in what to him is a foreign language. He is apparently unconscious of the necessity for submitting his manuscripts to the revision of one who is a scholar of the English language. This self-confidence has led him into errors of expression which not only make his explanations difficult to follow, but has caused him to make declarations which have brought him within the toils of the American reviewers. One critic, who confesses that Dr. Heitzmann probably does not intend to convey such "notions," draws attention to the fact that in the work reviewed the office of the ovary is said to be the production of a principle, this principle being the ovum, this ovum being called an organ, and the organ a vesicle. This work is not a manual of histology, nor intended as such, but the student cannot fail to receive many aids to his study by perusing the book.

"A Manual of Histology," edited by Dr. Thomas E. Satterthwaite, Professor of Histology in the New York Post-Graduate Medical College, published by William Wood & Co., of New York, second edition, is a work of a different character to the one just described. I believe this work is already known in Europe as well as in this country where the author holds a high place among investigators in this department of original research. Dr. Satterthwaite has no startling theories to elaborate, but is thoroughly practical in all that he offers. The methods of one who has for years made histology his daily occupation must surely prove valuable to those engaged in similar work. The cumulative work of others and the whole literature of the subject have been tested by him, and all that proved valuable and useful has been here reproduced and explained, in the light of his own experience, for the benefit of future students. After explaining his methods, Dr. Satterthwaite takes the reader through a course of practical histology, and finally introduces over twenty original papers by physicians who have associated themselves with the author in producing this work.

Professor Burt G. Wilder, M.D., of Cornell University, in conjunction with Professor Simon H. Gage, B.S., of the same university, has produced a new manual on Anatomy, which will be of considerable service as a class-book, and to those who endeavor to acquire by unaided study a knowledge of the subject. The title of the book is as follows:—"Anatomical Technology as applied to the Domestic Cat, an Introduction to Human, Veterinary, and Comparative Anatomy." The work is published by Messrs. A. S. Barnes & Co., of New York. There are many reasons for making use of the cat for anatomical purposes in preference to other animals, and as the adult human subject is inconveniently large, and not easy to obtain, the course of study offered by Professor Wilder may be followed with advantage by medical students as a preliminary training in anatomical manipula-

tions. The work of Mr. St. George Mivart, "The Cat," etc., is an admirable monograph, and describes the entire structure of the animal. It, however, makes frequent and wholly unspecified substitutions of human anatomy for that of the cat, and gives no practical directions for the student. Professor Wilder does not assume any previous knowledge on the part of the reader, but as a practical teacher leads the student from the simple to the complex, and offers a preliminary training in the best methods of preparation and preservation, which is worthy the study of all engaged in such investigations. Nearly one hundred and fifty pages are devoted to Professor Wilder's methods, and knowing as I do his skill in this department, I suggest that no higher model for the perfect construction and equipment of a dissecting studio can be found than the one he describes. The work is profusely illustrated with original drawings made specially for this purpose, and they may be relied on as accurate. Perhaps minor errors of observation and interpretation may be found in the text; but I think the reviewer who critically examines this work will have some difficulty in tracing inaccuracies of any magnitude.

New York, December 30th, 1882.

ACTION OF POTASH ON ALBUMEN.

To the Editor of THE LANCET.

SIR—I am far from desirous of entering the arena of controversy. Still I would venture to submit to the notice of your readers a few experiments on the action of a potassic hydrate solution on ov-albumen. A solution of pure potassic hydrate was prepared, the water employed for the purpose being twice distilled, and absolutely free from ammonia. The solution was boiled for half an hour, filtered through asbestos, and again boiled for an hour. It had a specific gravity of 1.5488.

Experiment 1.—Some ov-albumen was treated with two to three times its bulk of the potassic hydrate solution. Before heat was applied a small quantity was tested with a solution of lead acetate, with no appreciable result. To the remainder of the solution heat was applied, and it was allowed to boil for two minutes. On being again tested with the lead acetate solution a copious black precipitate of lead sulphide was thrown down. During the application of the heat a piece of lead paper, and a second piece of paper moistened with nitro-prusside of sodium, were placed in the neck of the flask, but the results were entirely negative.

Experiment 2.—Some ov-albumen was treated with about ten times its bulk of the potassic hydrate solution. It was tested with a solution of lead acetate at various stages with the results indicated:—(a) Cold. Result: No action. (b) At the moment of its registering 100° C. Result: A slight yellow discoloration, but no precipitate nor blackening of the solution. (c) After five minutes' active boiling. Result: The solution became of a reddish-brown color. (d) After ten minutes' boiling. Result: A slight but definite precipitate of a reddish-brown color. (e) After fifteen minutes' boiling. Result: A precipitate of a dark-brown color. (f) After thirty minutes' boiling. Result: A dense black precipitate proved to be lead sulphide. (g) After two hours' boiling. Result: Similar in all respects to what occurred after thirty minutes' boiling.

Throughout these experiments no traces either of sulphuretted hydrogen or of ammonio sulphide were set free from the solution. The conclusions I submit are manifest:—

1. That by the action of a boiling solution of

potassic hydrate on ov-albumen an alkaline sulphide is formed.

2. That this alkaline sulphide is not ammonio sulphide.

3. That with strong solutions of albumen the formation of the sulphide takes place rapidly, but that with dilute solutions it occurs more or less slowly, according to the quantity of albumen present.

Lastly, I would notice that the series of tints observed in Experiment 2—viz., yellow, reddish-brown, black—corresponds to the tints observed when sulphuretted hydrogen is first passed through a dilute lead solution—i.e., during the short interval that elapses before the black lead sulphide becomes actually formed.

I am, Sir, your faithful servant,

C. MEYMOTT TIDY.

Mandeville-place, W., Jan. 24th, 1883.

DILATATION OF THE FEMALE URETHRA.

To the Editor of THE LANCET.

SIR—In a clinical lecture on "Calculus in the Female Bladder," published in your valuable journal, Mr. Heath is accredited with the following words:—"I proceeded to dilate the urethra with a pair of polypus forceps and then introduced my little finger, and subsequently my forefinger, without difficulty. In this rapid dilatation there is, of course, some laceration, and it is usually upwards under the pubes and *does no harm*" (the italics are mine). This statement coming from so distinguished a surgeon, is, I think, calculated to do much harm, unless properly interpreted. Although so fortunate perhaps as not to have met with a mishap in his own practice, I am sure Mr. Heath does not intend to convey the idea that dilatation of the female urethra carried to the extent of admitting the forefinger, and to laceration, does not carry with it more or less danger of permanently impairing the retentive power of the bladder. It is undoubtedly true that the urethra and neck of the bladder is, in some females, susceptible of remarkable dilatation. In an operation for the removal of a soft villous growth from the bladder of a female, Winckle introduced both fingers and forceps into the viscus, the urethral mucous membrane was fissured, and yet none of the 150 grammes of water injected after the operation escaped from the bladder. In a similar operation by Schatz, although the urethra was dilated to an extent admitting two fingers, she could not retain her water one hour after the operation, though she soon regained the full tonicity of her sphincter; but, on the other hand, it is well known that this *not difficult* operation has been responsible for a great deal of suffering and misery in the protracted, and, in some instances, permanent incontinence of urine which it has occasioned, and rather than inculcate a feeling of safety, the novice should be warned against repeating an accident which has occurred in most experienced hands. That laceration of the urethra occurs, as a matter of course, is not to be wondered at when we consider the rude instruments that are made to serve the purpose of urethral dilators. In order to conform to the conditions by which alone a maximum degree of dilatation, without laceration, can be accomplished, the expansive force of the dilator should be distributed equally over all parts of the circumference of the urethra, by the unrolling of rounded blades, and not upon two or three sides of the canal as effected by the uterine dilators, polypus and bone forceps, so commonly employed. Again, the dilatation must be as gradual as it is continuous and uniform; that is, the degree of force ex-

erted should be carefully regulated to the amount of resistance to be overcome. An instrument providing for the conditions aforesaid is constructed by Tiemann & Co., of this city, and has been used here with great satisfaction for several years. It is both dilator and speculum. When closed it is 39 mm. in circumference and is capable of expansion to $6\frac{1}{2}$ centimetre.—Yours truly,

ALEX. W. STEIN, M.D.,
Surgeon to the Charity Hospital, etc., N. Y. City.
New York, Jan. 10th, 1883.

THE EFFECT OF TEMPERATURE UPON THE STAINING OF THE BACILLI OF TUBERCLE.

To the Editor of THE LANCET.

SIR—In one or two of the recent communications to your journal reference has been cursorily made to the influence of temperature upon the staining of the bacilli of tubercle, but sufficient prominence has not, I think, been given to this most important fact. With active staining fluids of the best kinds, and with material rich in bacilli, failure may result as a consequence of the fluids being maintained during the process of staining at too low a temperature. This has been a common experience during the recent cold weather; even the temperature of a moderately warm room at this time of the year is too low to give uniformly good results. I endeavored at first to obtain the necessary temperature by placing the capsules containing the preparations and fluids near the fire upon the hob or hearth, and although many of the results were highly successful, some failed, for it seems to be the case that not only too low a temperature, but even too high a temperature, may lead to failure. A water-bath is the apparatus best fitted for the purpose, as the temperature can in this way be easily maintained at about 100° F. for some hours; or if the expense of a water-bath be too great, an apparatus quite sufficient for the purpose may be made out of an ordinary hot-water dish or tin, upon which the preparations are placed, covered by a tea-cosy or a cap of felt or flannel.

Koch's experiments have shown that the temperature is all-important in the cultivation of these bacilli; and it is interesting to find that the same temperature (about 100° F.) at which they grow best is also that at which they stain best.

I make this communication in the hope of saving others the vexation and lost labor which ignorance of the fact long caused me.

I am, Sir, yours truly,
SAMUEL WEST,
Physician to the Chest Hospital, Victoria Park.
Wimpole-street, W., Jan. 8th, 1883.

ANTHRAX.

To the Editor of THE LANCET.

SIR—In an annotation in a recent issue you draw attention to the fact that, contrary to the generally received opinion, the placenta does not always constitute an impassable barrier to the passage of the bacilli of anthrax from the blood of pregnant animals to that of the foetus. In corroboration of that statement I may tell you that during the past summer while investigating an outbreak of anthrax in a flock of forty ewes—produced by the carcass of an anthrax sheep

buried in the pasture ground the previous summer—I found well-marked anthrax lesions in the foetuses of three ewes which had succumbed to the affection; and not only this, one or two of the animals aborted and recovered: it was also observed that most of the ewes which had lambed before the symptoms of the disease were shown recovered and did well. This case only confirmed strongly the opinions I had previously entertained in reference to this matter.

I am, Sir, yours truly,
THOMAS WALLEY,
Principal, Royal Dick's Veterinary College.
Edinburgh, Jan. 19th, 1883.

HAZELINE IN PROLAPSUS ANI.

To the Editor of THE LANCET.

SIR—A widow lady, aged about forty years, has suffered for several years with prolapsus ani of a severe character, attended with frequent hæmorrhage. About a fortnight ago the bleeding was very profuse, so much so that wine and brandy had to be given to her frequently to keep life in her. All remedies had been tried by her medical attendant, Mr. Hutchings, of Southborough, and failed to arrest the hæmorrhage for any time. I wrote and advised them to try hazeline, and found it has just been tried with great success, all bleeding having stopped, and there has been no return of it. The patient is recovering.

I am, Sir, yours, Etc.,
G. HOTHER, M.R.C.S.
Lewes, Nov. 15th, 1882.

KEROSENE OIL.

To the Editor of THE LANCET.

SIR—A few days ago I was summoned hurriedly to see a child, between one and two years of age, who had swallowed accidentally some lamp oil (kerosene). As the amount swallowed was very small, and readily induced vomiting, I contented myself with causing further vomiting, and administering castor-oil. On looking up the subject afterwards for information, I was unable to come across anything bearing on it. Therefore I have addressed myself to you, and shall feel greatly obliged to any of your readers who will answer the following questions:—1. What is more or less the analysis of kerosene-oil? 2. Is it poisonous, and if so in what dose and with what symptoms? 3. What medicine would it be judicious to administer as an antidote, or partial antidote, if any?

I am, Sir, yours truly,
TROPICUS.

"PHYSICIANS' PRESCRIPTIONS."

To the Editor of THE LANCET.

SIR—It is singular that there should be so much difference of opinion on this subject. If we look at the case accurately, the whole question seems to lie in a nutshell. A patient consults me—that is, seeks my aid. Why? To rid him of an ailment or to relieve his suffering. To do so I probably employ a combination of certain drugs, and I give a chemist written directions—the prescription—what drugs to combine and how. Clearly the nature of my prescription is a matter of no concern to the patient; his business is to use the means I prescribe for him. His right of

property extends solely to the bottle of medicine he receives from the druggist by my direction, and no further. The prescription itself, if it belongs to anyone, belongs to me, otherwise the patient might as well claim the knife with which I amputate his leg. He is allowed to retain the prescription simply as a matter of convenience for reference, for future repetition, and for identification; and I do not retain it, because it is probably of no further use to me. But curiosity, which in this case has its foundation deep in the instincts of human nature, leads a patient eagerly to scrutinize my prescription; if there is something in it he does not understand he often asks me for an explanation, just as another patient will not hesitate to inquire as to the contents of the bottle I may hand to him in the surgery. Both wish to have a hand in their own treatment, a desire which, like much of the meddlesomeness which often hampers the physician, springs from the all-powerful instinct of self-preservation. But it is absurd to suppose that the possession of a prescription confers on the possessor the right to use it on himself or on others at his own discretion.

I am, Sir, yours obediently,

W. J. TRENTLER, M.B. Edin.

Fletching, Jan. 30th, 1883.

LIME-JUICE AS AN ANAPHRODISIAC.

To the Editor of THE LANCET.

SIR—Having for some time been employed as surgeon in the mercantile marine, I have often heard it stated amongst the sailors that lime-juice acts as above; and on the voyage home I have known sailors positively refuse to take it solely on that account. Would any of your readers who have been at sea kindly give their experience on this point. By way of experiment, I tried it upon myself for a month, without any stimulant whatever, and in my own case, to my astonishment, it acted as "Jack" maintains it does.

I am, Sir, yours respectfully,

NAUTILUS.

News Items, Medical Facts, &c.

DR. AUSTIN FLINT has recently delivered a course of lectures on Auscultation and Percussion in Philadelphia. He has at these lectures demonstrated that most of the various sounds elicited by percussion and heard in auscultation may be produced and studied artificially with great ease. In his closing lecture he recommends that students should be made familiar with the sounds in this way, their character and mode of production, before passing on to actual clinical demonstrations of them.

EUROPEAN TRAVEL.—Persons contemplating a trip to Europe, or any other part of the Globe, either alone or with excursion parties, will find it to their advantage to investigate the numerous facilities offered by THOS. COOK & SON, the well-known Excursion Managers, of 261 Broadway, New York.

Full particulars of their arrangements will be mailed free, on application, to any one interested.

A DRESS has recently been exhibited at the rooms of the National Health Society, Berners-street, intended for the protection of sanitary visitors, nurses, and others who are compelled to enter

the apartments of persons suffering from infectious disease. It is made of glazed mackintosh, and completely covers the wearer, only the hands and face being left unprotected. It is stated that by the use of this garment the necessity for changing the ordinary attire is removed, and that the danger of communicating the disease is obviated. As often as may be convenient it may be cleansed with disinfectants. A respirator formed of medicated cotton-wool between two layers of thin net is added to the costume. After being used the cotton-wool is burnt and the net washed.

PATHOGENESIS OF EPITHELIUM.—Dr. Carl Hempel Reed, Resident Physician at the Philadelphia Hospital, has arrived at the following conclusions after a lengthened investigation of the pathogenesis of epithelium, with special reference to the formation of cancer:—1. Primary true cancers are found only in locations where there is pre-existing epithelium. 2. No cancer has been proved beyond doubt to have originated heterotopically. 3. The cicatrization of cancers explains the young connective tissue infiltration. 4. Young connective-tissue cells or white blood-corpuscles are never seen inside the alveoli. 5. The epithelial cancer-cylinders are independent of the connective tissue. 6. The endothelial ensheathments of connective-tissue trabeculae forming the alveoli are intact. 7. Secondary cancers have a concentric growth. 8. The proliferating power of epithelium normally is greater than that of any other tissue. 9. The results of the experiments show that the epithelial covering in the healing of ulcers is exclusively derived from the epithelium of the border, a most conclusive proof of this being the gradual advancement of the pigment from the borders of the healing ulcer; this fact, by analogy, forming a strong testimony in favor of the epithelial origin of cancer. 10. The transformation of connective-tissue cells into epithelial cells, in extra-uterine life, does not occur, physiologically or pathologically.

SUBACUTE ATONIC DYSPEPSIA.—"The preparation I have found to answer a most admirable purpose in such instances is neither strictly a food nor a medicine, but a sort of nondescript, betwixt and between. I allude to maltine, pepsin and pancreatine. As is well known, it is the half-way digested albuminoids and saccharine elements of wheat, barley and oats. Largely abounding in diastase and charged with the elements needful for carrying on the digestive process, all that is needed to complete the gastric process on a small quantity of appropriate food is heat and the vermicular action of the stomach.

On more than one occasion have I noted, during the past few years, the invaluable properties of the above preparation, after all other resources had failed. For the debility succeeding the acute diseases of those whose stomachs are inherently weak, or for the irritable and weak state which the long continued administration of medicines for some other disorder oftentimes engenders in the digestive organs, for the failure of energetic action during exhausting processes—as lactation, or large suppurative discharges, as well as for the gastric feebleness often attendant on tuberculosis, peptic maltine fills a place that no other preparation does, and in a truly satisfactory manner. It is altogether constructive; it is bland, even more so to the stomach than any food; it is not nauseating."—J. R. Black, M.D., in *Cinn. Lancet and Clinic.*

NEW YORK, MAY, 1883.

Presidential Address

DELIVERED AT THE

CLINICAL SOCIETY OF LONDON,

On January 26th, 1883.

By ANDREW CLARK, M.D., LL.D.,

Physician to the London Hospital.

GENTLEMEN—Another epoch in the history of the Clinical Society has come to an end, and a new epoch begins to-night with us. Standing thus between the past and the future—between the work which has been done, and the work which lies before us to do—the opportunity naturally offers, and we may profitably avail ourselves of it, to inquire somewhat concerning both. On former occasions of this kind you have been treated to dissertations on subjects occupying at the time the attention of the profession, to discourses on what may be called the “philosophy of clinical medicine,” to delineations of the sorts of knowledge necessary to continued advancement in our art; and to eloquent exhortations to active, purposive, honest, clinical work. To-night for the short time that I shall presume to stand between you and the business which we are assembled to consider, I shall take humbler ground, and contenting myself with a short survey of the completed labors of the Society, I shall endeavor to elicit therefrom such fresh helps for future guidance as may enable us to make our printed Transactions still more worthy of the work wherewith we are occupied, and of the workers therein.

It seems to me after a careful examination of the contributions made to the Transactions of the Society during the reign of my illustrious predecessor, that both in matter and in manner, in abiding interest and in clinical importance, in fertility of practical suggestions and in successful boldness of the operative procedures recorded therein, the volumes embodying those contributions will bear favorable comparison with any like number of volumes which have been issued before them. I have discovered in this later work no decay of earnestness or of strength, none of faith or of knowledge, none of foresight or of judgment; and in some ways, as in the recognition of clinical affections unconnected with sensi-

ble anatomical changes, it has taken, as I at least am convinced, higher and truer ground.

Examining the whole series of our Transactions, and calling to mind the character of the discussions elicited by many of the papers, one cannot fail to become impressed with a vivid sense of the great and growing importance of the work which the Society is silently but surely doing. The general good results of the Society's work are now so obvious and have been so often mentioned that they need for remembrance only the barest notice. We see how, through diversity of inquiry, community of work, unity of purpose, and severity of procedure, we have improved our methods, added to our knowledge, established new connections, multiplied our resources, settled a surgical revolution, and widened, deepened, and in some quarters transfigured our views. All this is plain, and the statement of it may be open to the accusation of commonplace. But what is not so plain, and what is not commonplace, is the influence which the Society has exerted and is exerting upon the scientific character of individual workers; and this, although less obvious, is not less important. The Society has improved the scientific characters of good workers; it has implicitly exposed and repressed bad workers; and it has framed for the guidance of all alike a standard of work which is sensibly elevating the profession and benefiting our art.

In the work of the younger members of our profession I see, or at least I think that I see, greater care, patience, and accuracy in observation, a more rigorous fidelity in the record of therapeutical experiments, wiser caution in speculation, graver deliberation in judgment, a growing frankness in the confession of oversights and errors, increasing severity in the siftings and testings of their own conclusions, a readier effacement of the personality in the work, less unseemly eagerness for mere priority of publication, a deepened sense of the responsibilities of premature speech and writing, a rapidly abating bitterness in the conflicts of opposing views, a more robust and manlier spirit of scientific life, and less reluctance in making admission that there is no unconditional truth in the results of our inquiries—no finality in our finished work, no creed in medicine. But the Society has done more than train good workers; it has repressed bad workers. For one competent and conscientious worker there are ten who are incompetent and unconscientious, and who in divers ways hinder our progress and spoil our present

possessions. Intolerant of the patient and painful toil of the true worker, acute in power of superficial observation, gifted with a certain showy versatility, quick at catching hold of new ideas, ingenious in guessing, crude in experiment, loose in therapeutic trials, hasty in speculation, strong in dogmatic assertions, accomplished in the transfiguration and use of other men's work, finding what they want wherever they seek it, unhindered by difficulties, facile in speech, ready in writing, thirsting for notice, such men, now, alas, not uncommon in medicine, begot papers so quickly that they can have no necessary relation to time, observation, or thought, and flood our literature with their unworthy if not unvarnished lucubrations. The favorite hunting-ground for such men is therapeutics, and their favorite sport is the catching of remedies, the putting of them to new uses, and the setting forth of their successful results. These men discern no difficulties and have no failures; they can illustrate their successes by scores of cases, and explain them by the most ingenious theories. There is scarcely any limit to the extent or the variety of their achievements; and as they flaunt along in the fulness of self-satisfaction, they look down with pitying condescension upon those in the straight and narrow way who conscientiously toil with small success in seeking after truth, but who, nevertheless, missing the praise of men, find strength and solace in their sacred search.

Another great work of our Society has been, and continues to be, the gradual unfolding of the exact relations which morbid anatomy and, incidentally, experimental pathology should hold to clinical medicine. These two chief servants of our art, excited and carried away by their marvellous successes, and assuming a joint sovereignty over our art, look down with condescending superiority upon clinical medicine, ridicule her claims to supremacy, scoff at her empirical distinctions, reproach her with being unscientific, and strive to torture her into a slavish subjection to their theories. But the true relation is not this; it is, indeed, the converse of it. For the structural change is not disease, it is not co-extensive with disease; and even in those cases where the alliance appears the closest, the statical or anatomical alteration is but one of other effects of physiological forces, which, acting under unphysiological conditions; constitute by this new departure the essential and true disease. For disease in its primary condition and intimate nature is in strict language dynamic; it precedes, underlies, evolves, determines, embraces, transcends, and rules the anatomical state. It may consist of mere changes in the relations of parts, of rearrangements of atomic groupings, of recurring cycles of vicious chemical substitutions and exchanges, of new conditions in the evolution and distribution of nerve force, and any or all of them may be invisible to the eye, inseparable from life, and indiscernible in death. Undoubtedly the appearance of a structural alteration in the course of disease introduces a new order of events, sets in action new combinations of forces, and creates disturbances which must be reckoned with, even as mechanical accidents of the pathological processes. But always behind the statical lies the dynamic condition; underneath the structural forms are the active changes which give them birth, and stretching far beyond the limits of pathological anatomy, and predated by the actions and interactions of multitudinous forces, there is a region teeming with manifold forms of disease unconnected with structural change and demanding the investigation which it would abundantly reward. It is in this mysterious and fertile region of dynamic pathogenesis that

we come face to face with the primitive manifestations of disease, and learn how much knowledge from various sources is needed to understand it aright; it is here that we see how, without help from physics, chemistry, and biology, collecting, converging, and meeting in a common light, no single problem in disease can be completely solved; it is here that we are made to comprehend how the nature of a pathological product cannot be determined by its structural characters, but by the life history of the processes of which it is only a partial expression; it is here that we observe how, in therapeutic experiments, the laws of the race are conditioned and even traversed by the law of the individual; and it is here that we discover how clinical medicine is to become a science, and how she is already, beyond question, at once the mother and the mistress of all the medical arts.

And here in this relationship of processes to products, although only incidentally and inferentially touched by them, I must advert for a moment to the results of pathological experiments. As to their necessity and value in the progress of medicine there cannot be any justifiable doubt. But for whatever purpose they may be employed, however carefully they may be designed, and executed, however successful may be the precaution taken to exclude error, experiments have their subtle difficulties and dangers which are perilous to truth and cannot be wholly averted. By the prestige of precision, which often undeservedly they possess, undue weight is attached to their results, and by the assumption that in like conditions the results would be the same in man as in the lower animals, flagrant errors are committed and currency is given to false or inadequate generalizations. The experimenter interprets the results of his experiments by the light of their structural results; he forgets, or he ignores, the life-history of the processes by which they have been evolved, and he takes no account of the fact beyond controversy, that different clinical states find occasionally the same structural expression. In such circumstances doubt is inevitable, and it is only to clinical medicine that any just appeal for its solution can be made. To her at last all such experiments must be brought for trial; she must be their examiner, critic, interpreter, user, and judge. And no results of experiments can be made of any avail to medicine, or be used with safety in her service, until they have been filtered through the checks and counter-checks of clinical experience, and have responded to the test and counter-tests of clinical trial. And had these principles exerted their just influence in the recent debates concerning questions of this kind, we should not have had a seton in the neck of a man taken as the parallel of a seton in the neck of a guinea-pig; we should not have had the artificial tuberculosis of the rodent declared to be identical with the natural tuberculosis of the child; we should not have had grey tubercles and caseous pneumonias pronounced, on the grounds of mere likeness of structure, to be of one and the same nature; and we should have been spared the sight of science drunken with success and drivelling with prophecies, soliciting the public on the common highway.

Of such examples of good work done by the Society there are many more known to myself than I could give if time permitted, and doubtless there are many more known to others than I could not give because they have escaped my notice. But I have given enough to justify, and even to require, a little reckoning of our shortcomings. Happily, the Society has still its imperfections; and as they are unlikely to be easily remedied we shall not

lack motives to endeavor, nor miss the reward which comes from rightly endeavoring.

One of the defects which I notice in the Transactions of the Society is an incompleteness, outside the immediate objects of interest, in the history of many of the cases recorded therein. If we are to make real use of a case, and if the case is to help us with other cases to make great and true advancement in our art, it must be given to us as a complete whole. We must have not only the family and personal history, but we must have also the nature, assemblage, and progression of symptoms elucidated by all the assistance that can be had from physics and chemistry, from the spectro-scope and microscope, from physiology and experiments. I do not presume to say that incomplete cases are either valueless or unwelcome, for doubtless they have often an interest and value peculiarly their own; but I do say that for all the higher and truer objects of medicine our earnest and unflinching endeavor should be to make every case as complete as the collateral knowledge of the time will enable us to make it. Hence the necessity and value of purposive, concurrent, and co-operative work. Hence arose the great medical renaissance of Germany, when Virchow and Brücke, Ludwig and Traube, Meyer and Lieberkühn, Lehmann, and Helmholtz, bringing together the results of their critical and experimental studies in various departments of knowledge, resolved, as if by magic, some of the obscurest problems in physiology and medicine. But of all the defects in the work of the Society, the one which I consider to be at once the most important and the most inexplicable is the seemingly studied disregard, in the treatment of a patient's malady, of these minute conditions of his daily life which practically make or unmake health. So that special management being almost nothing, and special medication almost everything, it would seem as if physiological principles were of no account in therapeutics. But a more critical study of disease will soon convince us that this inference is unsound and its application incorrect. Putting aside for the moment inherited affections and parasitic maladies of whatsoever sort, I shall assume that chronic disease, a state of parts, and not a thing interposed between them, is the eventual outcome of continued violation, conscious or unconscious, of physiological laws as they exist for the race, or as they are conditioned by the peculiarities of the individual organism. I shall further assume that those violations are not exceptional and gross, but daily and minute, and that their effects, infinitesimal from day to day, become visible only after longer periods of time, and so escape recognition, except by those who are trained to discern the casual connections of subtle things. And I shall furthermore assume that the organism, in virtue of the inherent forces maintaining its solidarity, tends to repair existing, and to repulse threatening disorders, and that when placed in favorable, and liberated from unfavorable physiological conditions, this tendency issues and ends in successful action.

And now let us take for illustration a case of primitive uncomplicated gastric catarrh. Assuredly it does not come without a cause, and it is not introduced from without, but begotten within. It is in fact engendered out of a more or less prolonged and perhaps petty violation of the laws of stomach digestion, and it is maintained by conditions which, although apparently too trivial to be worthy of notice, are yet sufficient to hinder the formation of healthy peptones, and to traverse the reparative powers of the organism. What is ordinarily done in such a case? The patient is told in a vague sort of way to have a light and

nourishing diet, to take daily exercise, to avoid anxiety and overwork, and to try bismuth and alkalies with an occasional alterative aperient. Now, speaking, if I may be permitted to do so, from my own experience, it is certain that in such a case management is of more moment than medicine, and that without a rigid and even minute obedience to the physiological conditions of healthy digestion, the chances are small of a speedy and permanent recovery from the gastric catarrh. But the instruction of a "light and nourishing diet" admits of the widest diversity of interpretation, and with the most loyal desire for literal obedience, the patient, according to his age, habits, and station in life, may be unwittingly guilty of doings the most conflicting and injurious. He may eat too often or too seldom, too hot or too cold, effervescent or still. And without a conscious but yet real and great departure from the intention of his instructors, he may frequently refresh himself with cups of tea and coffee and make glad his heart by incidental glasses of wine or of beer.

Now there is a right way and a wrong way in the management of every such case; and although they lie so near each other, and are so much alike that the distinction between them is not easy of discernment, it is necessary that the distinction shall be made. For it is upon giving or not giving a correct and minute attention to the physiological conditions affecting the quantity, quality, and character of the solid and liquid food, the times and the circumstances of eating and drinking, the amount of exercise, work, and sleep, and the adequate discharges of excrementitious functions, that our work will succeed or fail, that our case will turn for evil or for good, and that the patient will either recover his health or drift into permanent valetudinarianism.

If time permitted and the occasion would justify it, I could easily produce from the records of our common experience in every department of medicine illustrations the most various and conclusive of the peril of neglecting and the profit of following minute physiological considerations in the treatment of disease. On this occasion I shall content myself with one.

Some eight years ago I was summoned to a consultation in South Kensington, where, in presence of the patient and his family, I met Dr. Andrew Stephen and Dr. Taylor. It appeared that the subject of our consultation, having been ill for many weeks, and growing rapidly worse, had been brought from Wales to London for further advice, and that the advice given was opposed to the feelings and convictions of the patient and his friends. The family therefore refused, without the help of another opinion, to carry out the proposed treatment; accordingly, with the acquiescence of the doctors, I was summoned to examine the patient, and to state my views, without previous consultation with my colleagues, but in their presence. The patient, a tall, stout man of about sixty, with flushed face, suffused eyes, anxious countenance, and swollen legs, sat leaning forward in an arm-chair, partially undressed, breathing laboriously, and apparently in much distress. He complained of shortness of breath and palpitation, of confused sensation in his head and occasional dizziness; of general weakness and of indescribable depression. The patient had a loaded tongue, with fetid breath, and, although troubled with nausea, was able to take freely of food and drink. The abdomen was distended and the liver distinctly enlarged. There were frequent discharges of fetid gases from the bowels. The feces, discharged twice or thrice daily, were dark, offensive, and unformed. The urine was scanty, pale, faintly acid, of a density of

1010, and slightly albuminous. The heart was large, flabby, murmurish, frequent, quick, and irregular in time and force. The pulse was small, thready, irregular, and beating over a hundred times in a minute. The legs were cedematous, bluish-red, and cold. The cervical veins remained continuously distended. Both lungs were congested at their bases, and there was frequent cough, with frothy, and sometimes sanguinolent expectoration. Nothing worthy of note was discovered in the nervous system.

Inquiring now as to the treatment which was being pursued, I was told that in the opinion of all who knew him, and of all the doctors except the last who had been consulted about him, the patient was a man of naturally delicate constitution, that he needed constant keeping up, and that his chances of life were in direct proportion to the amount of support that he could take. Accordingly he was taking food and wine every second hour, had iron, quinine, and strychnia three times daily, and, being increasingly thirsty, he drank milk-and-soda water without much regard to frequency or amount. Questioned as to my opinion of the patient's malady, and urged by my colleagues to say exactly what I thought, I replied that he was a man with deteriorated but not seriously diseased tissues and organs, and that he was in peril of death, not so much from his malady as from the means used for its cure, that he was being poisoned by food and wine, that he was in the condition of a fire having more coals put upon it than it could burn, and that his chimneys being choked he was in near danger of being suffocated with his own smoke. My colleagues agreeing with this view of the case, and the patient, after much discussion and explanation assenting, he was placed upon a precise and severe regimen. He was ordered to have four simple nursery sort of meals in the course of the day, to have an ounce of brandy diluted with eight parts of water at dinner and supper, to be restricted to two pints of liquid in the course of the twenty-four hours, to take nothing of any sort between meals, and as soon as he was able to move about the rooms in which he dwelt. In the way of drugs he was directed to take for a week or longer a grain of calomel at night, followed by a salient aperient on waking in the morning, and to have twice or thrice daily, two hours after food, infusion of gentian with bicarbonate of potash, iodide of potassium, tincture of digitalis and aromatic spirits of ammonia. For the first three days he was no better for this treatment. It tried him severely through the restriction of his liquids, and, declaring himself worse for it, he threatened to discontinue it, and to return to his former ways. But on the fifth day he began to improve, and then, his confidence being gained, there was no further difficulty in continuing the treatment, which, when digestion improved, was added to by the administration of reduced iron with meals. At the end of three months the patient declared that he was well, and all that could be said against him was that he had a weakish heart, that he was breathless upon exertion, that he had rather inadequate kidneys, and that to maintain his sense of well-being he was compelled to live by rule. This rule was a mid-day dinner with an ounce of brandy in half a pint of water, a moderate breakfast and tea, with eggs, or poultry, or fish, extreme moderation in the use of fluids, tepid sponging, warm clothing, gentle exercise, and early hours. Within a year I heard of the patient being in fair health and managing his ironworks in Wales. What I have since heard of him from time to time is instructive. Occasionally, losing his faith or lacking strength to follow his rules, he returns to the freedom for which he

longs, frequents society, dines late, rejoices again in his wine, and has all that his heart desires. For a time all goes merrily and well, and he breaks sarcastic jokes over the heads of his physicians. But sooner or later this seeming well-being ceases, and his troubles reappear. The urine diminishes in density, and becomes albuminous; the heart loses its strength and regularity; the breathing is oppressed; the nights are sleepless and the days depressed; till at last, after much suffering, his obstinacy is conquered, and reconvinced, and humbled and penitent, he returns to his obedience and again recovers his health.

Such cases are common enough, and my experience forbids me to doubt that in fevers and inflammations, in hæmorrhages and acute diseases of every sort, the issue of particular cases turns oftener than we are perhaps ready to admit upon an adequate understanding of the physiological principles applicable to the removal of the conditions imperilling life, and upon the resolution and patience, the minuteness and fidelity, with which they are enforced. Such considerations are true and important, not only in diseases jeopardizing life, but also in common disorders, which, although devoid of serious peril, invade our comfort, hinder our work, and dull our joy in life. I do not forget that through hereditary influences and unsuitable but inevitable environments many persons are doomed to be constantly ailing without being really ill; that their normal state is one of suffering; that no physiological readjustments and no specific medication can give to them the pleasant sense of health; and that attempts to effect what is impossible issue only in greater suffering or in disaster. But making full allowance for such cases, there remain countless numbers who are willing and eager to make any and every sacrifice necessary to recovery, and who are left to continue in suffering because the physiological principles and compensations applicable to their relief are derided, disregarded, or denied.

Reviewing anew the completed Transactions of the Society I am struck with the inadequate representations found therein of that interesting and instructive group of clinical affections which is unconnected, except casually, with sensible structural alterations of the tissues and organs. The group contains numerous members of divers sorts, and I cannot doubt that every one of them would repay thorough investigation, with fresh additions to our knowledge of the origin, the nature, and the relations of disease. Many of them, familiar to experienced practitioners, have no sufficient recognition in medical literature; and a full account of them all would contribute more than any other account that I can imagine to a just understanding of the relations of dynamic to static conditions, and of physiological to pathological processes.

Let me make mention of such members of this group of affections as lie nearest my thoughts at this moment. And, first, there is the morning agony of middle-aged nervous people, often the precursor of melancholia. A man awaking at early dawn is conscious of undefinable malaise and unrest; his mental and moral outlook become dark and gloomy; aching pains arise in the limbs; unable to lie still, he tosses restlessly about his bed; the malaise deepens into distress, and he groans; a cold sweat breaks forth over all his body; and then in a few minutes the attack subsides, and the patient finds himself in his accustomed health and spirits. In the second place, I will mention the temporary incomplete hemiplegias with aphasia, which, closely allied to migraine, occur often in women, and occasionally in men, otherwise healthy and strong. A woman, neither hysterical nor nervous, suddenly fails to see distinctly; the field

of vision is invaded by moving zigzag lines of light, arranged either in circles or in forms resembling the outlines of a fortification; there are slight ringing noises in the ears, and trifling confusion of thought; numbness follows about the tip of the tongue, on one side of the lips and mouth, in the right thumb, and more rarely in the right leg; the connection between ideas and their correlated words is interrupted; articulation falters; there is, perhaps, passing loss of power in the right hand or arm; the breathing and the pulsation of the heart are quickened; the feet and hands become moist and cold; and then, after a period of time varying from ten to thirty minutes, with or without a slight headache, the attack ends with a few deep sighs and a discharge of limpid urine. Curiously enough, when headache occurs early in attacks of this kind, and is severe, sickness soon follows; disturbances of speech, sensation, and motion seldom arise; and the distinctions which, in its fully developed form, separate this affection from migraine are obliterated. In the third place, there is the dry barking cough of boys and girls about the age of puberty. This curious but not uncommon affection is characterized chiefly by recurring paroxysms of a dry guttural cough, which resembles the barking and, occasionally, the howling of a dog. This affection is usually associated with various slight disorders of the nervous system, and with defects of will; it is greatly influenced by the emotions, and sometimes instantaneously cured by sudden surprise or shock; it is occasionally so distressing to others that servants, and even friends, cannot stay in the house in which the patient dwells; it is only in a small degree amenable to treatment; lasts from three or four months to as many years, and ends, in my experience, always, in complete recovery. In the fourth place, I would call attention to the cases grouped under the term renal inadequacy; cases in which, without discernible structural alterations of the kidneys, they are, nevertheless, incapable of producing a urine of sufficient density and of healthy constitution; cases in which the blood, getting charged with excrementitious matters, and nutrition and innervation becoming thereby disordered, the patients suffer in general health, fall immediately into peril from attacks of acute disease, and cannot, with ordinary chances of success or of safety, undergo a common surgical operation. In the fifth place, I will mention the numerous and important cases occurring among young persons in whom, under the strain of prolonged competitive examinations and great excitement of any sort, the urine temporarily falls in density, loses its healthy characters, and becomes albuminous. Of the young men competing for places in the Indian Civil Service examination, I have ascertained, by repeated personal examination, that more than a tenth becomes albuminuric. And, not to weary you further with illustrations, necessarily imperfect, of this group of affections, I will conclude with merely mentioning the glycosuric storms which, without sensibly damaging the body or materially impairing health, come and go throughout a lengthened life; the gouty spasms of the diaphragm so often mistaken for some affection of the heart; and those strange cases of antochthymia, in which the blood, when divided into minute streams, is ready to clot on the slightest provocation from the structures around.

Next in importance to the work of the Society are the manner and circumstances in which that work is done. Under these heads many reflections occur to me as worthy of being submitted to your consideration; but the time at my disposal is so short, and the list of cases for consideration so

long, that I must confine myself to the setting forth of a very few of them.

The general meetings of the Society have been well attended; but whilst the junior members have been conspicuous by their presence, the senior members have been conspicuous by their absence. This is much to be regretted for the sake of the work of the Society and the discipline of its members. The seniors themselves suffer in manifold ways from their non-attendance. They miss the stimulus which comes from contact with youthful enthusiasm; they slide into stereotyped habits of thought, expression, and work; they lose their receptivity; they ceased to adjust themselves to their ever-varying environments, and thus they become old, and the labor which should be life is transfigured into virtual death. The Society suffers; for it needs the large experience, the wide views, the sharpened insight, the cautious temper, the sober judgment of disciplined age, to control, regulate, and carry to their best issues the minuteness of detail, the flow of imagination, the hasty generalization, the speculative passion, and the dogmatic fury of our fervid youth. The pleas of pressing occupation and of consequent fatigue are doubtless true, but nevertheless they must be disallowed; for no good can be got without sacrifice; and the sacrifice of ourselves, even at the cost of suffering, is the only, or at least the chief, occasion of getting the strength which we need for the greater purposes of our lives.

Of late years there has arisen in the domains of general literature and of controversial theology a habit of dealing with the relations of ideas to words which is calculated to throw into confusion all the higher controversies of the time and to inflict serious injury upon letters, the advancement of knowledge, and even the moral life of man. Under cover of a particular word, connected by long usage and by common consent with a sufficiently definite idea, a new idea, totally different from the old, is introduced, and is then used as if the one had become merged into the other, and as if there were no doubt or difference between them. For example: By a religious man most people would understand a person devoutly loyal to his ideal of a Divine Ruler of the universe, and fervent in his endeavors to die to himself that thereby he might live to God. But in these days all this is being changed: a man who is emotionally interested in anything—in art, or physics, or science—is a religious man. His sanctity is to be measured by his fervor; and morality has just this relation to this religion that, if it interferes with its culture, so much the worse for morality, which is a defect or a disorder that forthwith must be thrust aside. Now this juggling with words and ideas—this throwing of dust into people's eyes so that controversies which cannot be settled may be stifled—this unpardonable sin in literature, is threatening to invade the realms of medicine, to confuse our discussions, and to render hopeless our progress in some departments of knowledge. For instance, the word tubercle is now often so used as to comprehend the most diverse ideas, and to give apparent reconciliation to the most conflicting views. One may not object to an author using in his works words in the sense, usual or unusual, in which he has defined them; but one must protest with all one's power against the habit of a man who puts on the clothes of another man and struts along the common highway pretending to be him.

A few more words upon a different aspect of the working of our Society and I will hasten to a conclusion. The cases recorded in our Transactions are for the most part admirable. It cannot justly be said of any one of them that it is destitute of

interest or of instruction; many are fertile in fresh expedients for treatment or conclusive in their bearing upon questions still contested or unsettled, and in not a few one finds the spell of original, creative, and far-reaching thoughts. But however highly we may rate the value of any one of those cases standing by itself, its value for every purpose conceivable in our relation to it would be doubled standing side by side with a record of the debate which the case had excited. For thus we should secure various views corrective or confirmatory of the position taken up by the narrator of the case, and we should obtain in this way what we can rarely, if ever, obtain in any other way, the ripe experience, judgment, and wisdom of busy practical and successful men. For the literary and practical faculties are seldom combined in one person, nay, in the course of time there often arises a sort of antagonism between them. The man who can observe, collect, classify, reason, invent, apply, is often through the direction of nature or the force of circumstances deficient in the qualifications necessary in one who is to speak and write with ease. His habit of accumulating and using knowledge for practical purposes weakens the power of methodical exposition, so that from his improving treasury we get fewer gifts, and the habit of continuous literary effort is not only neglected but shunned. And yet these are the very men whose knowledge is in an especial manner worth the getting; these are the men whose halting words straight from the watching and questioning of nature are oftentimes more precious than eloquent speeches; these are the men whose experiences worked into a few clear ideas, packed into a few awkward sentences and spoken in so many minutes, will sometimes bring to a conclusive close the discussions of many days. And when you cannot induce such men to write, you may tempt them successfully to speak, and the temptation will not be made more difficult, nor the responsibility in speaking less, by the knowledge that their words will be preserved in that storehouse of facts, experiments, and reflections which this Society will give to the generations that follow after this.

And as of like, although not equal importance, I shall venture to ask the Council to permit the publication in the Transactions of the reply made by the author of a paper to the criticisms which it has elicited. After reading in one of our journals the record of some interesting and important debate in which various, and perhaps contradictory, views have been advanced, we are told that "the author having replied, the Society adjourned." But what the author exactly said, how he dealt with the facts, cases, and criticisms adverse to his views, what he admitted or what he refuted, whether the case collapsed or succeeded, we are not informed. And thus, deprived of the most important evidence of the most important witness, we decide the case not according to evidence, which is incomplete, but according to prepossessions, which neither necessarily nor usually influence us aright.

And now that our work awaits us, let us turn to it with justly attuned minds. For surely the burden of it is not mere occupation or interest, not mere success or failure, not mere profit or loss, not mere distinction for ourselves, nor even honor for the profession to which we belong. The true and serious burden of our work as we smoothly say so often, and entirely realize so seldom, is the prevention of disease, the relief of suffering, and the prolongation of life. And this is the burden of it, not in a loose and general sense, but in a solemn and particular sense; it is the burden of it as it affects not merely many persons, but one per-

son, one with whom we have to deal as if he were the sole object of interest and importance in the world, as if all the momentous possibilities of life and death, of the preservation or the destruction of the family life, and of all the good or evil which might issue out of recovery or of death, were centered in him, and depending upon us. Important as our work thus is to the life and welfare of the individual and the family, it is not less important to the life and welfare of the State and the world. For this work, as it is sound or unsound, successful or unsuccessful, affects, for good or evil, the numbers of the population and its physical constitution, the supply of labor and the sources of wealth, the education of the young and the direction of their energies, the moral conditions of society and the objects of political organizations, the development of the race and the fulfilment of its destinies. Such reflections, common as they are, serve to remind us of what our familiarity with them makes us forget—the momentous and far-reaching influences of our work, and of the solemn responsibilities which lie upon us in undertaking and discharging it. Such reflections may further help us to cherish the spirit of self-sacrifice in active endeavors to overcome our ignorance of disease, till at last, with fulness more or less, knowing and foreseeing, preventing or controlling, stilling pain or curing disease, repulsing death and renewing the conditions of continuing life, we may justify the boast of our father, Hippocrates, and to men in their extremities of need give help like gods.

I cannot close these desultory and imperfect remarks without adverting to the honor which you have conferred upon me in electing me to the presidential chair. It is an honor which, although unanticipated and unsought, is not unvalued. I regard it, indeed, as the highest honor which I or any physician could receive. For titular honors may be got by Royal favor or the influence of a great Minister, or may fall upon one through accidents of position and of service. But this honor no favor, influence, or accident can purchase. It is a spontaneous gift of the profession, and the recipient of the honor must be free from grave reproach, and at least credited with some sort of merit.

I do not deceive myself with the thought that I am sufficiently worthy of this great honor, nor do I forget that there are others before me worthier of it than I. But I am not here to-night to quarrel with your judgment; humbly and gratefully accepting it, I shall strive to justify it by endeavoring in singleness of heart and fervor of purpose to co-operate with you in the divine work which you are doing for the relief of suffering, the advancement of knowledge, and the higher discipline of ourselves for the better service of both.

—THE magistrates at Kells, Ireland, were recently engaged in hearing a charge of indecent assault brought against Dr. Sparrow, medical officer, of Kells, by a female dispensary patient. Dr. Sparrow was accompanied in court by a number of medical men in the district. After the girl had been examined at considerable length, the magistrates unanimously dismissed the case, and held Dr. Sparrow free from any imputation. Defendant's counsel said that had the case proceeded Dr. Sparrow had in court many witnesses, medical and others, who could have established beyond a doubt that, so far from being guilty of the extraordinary charge made by the girl against him, he had simply done his plain duty as a medical man.

ABSTRACT OF

Jettsonian Lectures

ON THE

TREATMENT OF SOME OF THE FORMS OF
VALVULAR DISEASE OF THE HEART.*Delivered before the Medical Society of London.*

By A. E. SANSOM, M.D. Lond., F.R.C.P.,

Physician to the London Hospital, Senior Physician to the North-Eastern Hospital for Children, etc.

LECTURE II.

MITRAL REGURGITATION.

I HAVE to ask your attention this evening to the subject of the treatment of various conditions of disease associated with a certain imperfection in the mechanism of the heart—an imperfection of closure of the left auriculo-ventricular orifice at the time of systole, occasioning the reflux of a portion of the contents of the left ventricle into the left auricle, the mitral valve being inadequate to close the orifice. Pathological anatomy teaches that such result may be brought about by several varieties of morbid change: (1) By dilatation of the left ventricle without structural disease of the valve; so the free borders of the curtains are drawn upon by their circumferential attachments and prevented from a perfect apposition in systole. (2) By diseased conditions of the valve curtains, the tendinous cords, and fleshy columns, induced by endocarditis and the changes consecutive thereto. (3) By rupture of the valve curtains, cords, or columns, and their consequent incompetence. It has been supposed that rupture may occur from sudden strain in a healthy heart; but Drs. Wilks and Moxon have given strong reasons for the conclusion that there must have been some dilatation, at least of the left ventricle, previously; they consider that this accident is not of infrequent occurrence. (4) By atheromatous disease, patches of which may be observed upon the valve, with consecutive degenerative change, rendering it inadequate. (5) By ulceration of portions of the valve and the surrounding structures.

Mitral regurgitation is not, however, wholly to be interpreted by pathological anatomy. It is to clinical investigation that we must chiefly look for guidance. Of this condition a murmur at the left apex of the heart with the systole is the sign almost, though not quite, pathognomonic. The only condition with which it is likely to be confounded is, in my opinion, pericardial roughening at or about the apex. I have never known a difficulty about the differential diagnosis in the case of adults, but I have observed such difficulty several times in children. In cases of children I have repeatedly said that the quality, character, and situation of a systolic apical murmur will not declare with precision whether there is exocardial or endocardial disease.

Combined clinical and necropsic observation soon convinces us that in certain cases wherein we have determined from such physical sign that mitral regurgitation existed during life, no lesion indicating inadequacy of the mitral valve to close its orifice has been discovered after death. Moreover, in some cases where we have not only observed the sign mentioned, but where the whole category of signs, symptoms, and consecutive changes which experience has taught us to associate with mitral inadequacy, have been present, the autopsy has demonstrated no determinate lesion at the orifice.

It will best serve a practical purpose, I think, if we divide the cases in which the signs indicating mitral regurgitation are evident into clinical groups, discussing the bearing of the collateral signs upon treatment in each group. We shall thus consider the cases as we meet with them in practice.

I. A case presents itself manifesting signs indicating mitral regurgitation in the subject of marked *anæmia*. We have to inquire whether or no there has been antecedent disease, leading up to organic change at the mitral orifice. Supposing such signs are not in evidence, have we a right to assume that actual mitral regurgitation can be induced by the condition of *anæmia*, without concurring causes? The answer is, in my opinion, undoubtedly in the affirmative. In cases of *anæmia* and chlorosis a murmur is sometimes heard exactly in the site of that indicating mitral regurgitation. Assuming that in these cases there is a veritable regurgitation, how is such brought about? The explanation is, I think, given by the careful experiments conducted by Ludwig and Hesse at Leipzig, which have been admirably summarized by Dr. Donald Macalister.¹ The mechanism for the closure of the left auriculo-ventricular orifice does not reside in the valve curtains alone; the surrounding muscles of the ventricle have an active share, not merely in floating up the valve curtains, but in reducing the size of the aperture which these valve curtains have to close. It is not that the orifice is dilated, but that it is *insufficiently contracted*, the aid of the muscles of the wall of the ventricle which normally produce such contraction being lost.

It is important in regard to treatment to differentiate mitral regurgitation due to disease of the valves from that due to *adynamia* of ventricle, supposing a systolic apical murmur to be manifest in a markedly *anæmic* subject. The two signs I would most rely on as pointing to an *anæmic* causation of the murmur are: (1) an absence of notable cardiac dilatation; (2) a heightened tension in the systemic arteries. I have never known in these cases any marked improvement follow the administration of the usual cardiac tonics, such as digitalis and iron. In the cases attended with hæmorrhage it is, of course, of the first importance to arrest this at its source. Rest and the administration of assimilable food are no less important indications. In this connection I may call attention to the great value I have observed to attach to *supplementary alimentation by the rectum* in such cases. I have long tried the plan of using defibrinated ox blood for a nutrient enema, as advocated by my friend, Dr. A. H. Smith, of New York. In comparing results, however, with those in which artificially digested food has been employed, I felt that the balance of evidence is in favor of the latter plan. I have had prepared mixed peptone enemata—beef, milk, and farinaceous food—which have been proved to preserve a perfectly good condition for long periods. These have the advantage of being available at a moment's notice, it being only needful to render them diffident with warm water. From two to four ounces are injected slowly into the rectum, and repeated every three or four hours. In many cases I have caused to be added the dry ox blood (*sanguis bovinus exsiccatus*), in the proportion of a drachm to the ounce. I have lately, however, adopted a simpler plan with good results, using, instead of peptoned food, equal parts of warm milk and cod-liver oil as a nutritive enema.

In the treatment of cases of idiopathic *anæmia*

¹ Remarks on the Form and Mechanism of the Heart, etc., British Medical Journal, Oct. 28th, 1882, p. 825.

I have found no drug treatment so efficient as the administration of arsenic (Fowler's solution in small doses gradually increased). I have observed, as has been recorded by others, complete recovery, with the disappearance of the cardiac murmur, under such treatment, combined with rest and careful nutrition.

II. We will now assume that a systolic murmur is present in a person showing signs of a *neurosis of the cervical sympathetic*. It has been frequently noted that a murmur at the apex has existed in the subjects of exophthalmic goitre (Graves' or Basedow's disease); yet, on post-mortem examination, no disease at the mitral orifice has been discovered. In these cases anæmia may be present, but not of necessity. It is not casually related with the phenomena. Organic heart disease may co-exist, but such coincidence is rare. It is important to recognize, especially with regard to treatment, that in the subjects of Graves' disease mitral regurgitation occurs without valvular lesion. The record of fatal cases in which disease of the cervical sympathetic ganglia has been actually demonstrated in Graves' disease is now tolerably extensive. Troussseau, Cruise, and McDonnell, Keith, and Shingleton Smith have recorded cases in which some of the ganglia (usually the inferior cervical) have been enlarged, atrophied, or degenerated.

As regards treatment, in the cases which I have seen, ordinary tonics and digitalis have been of very little benefit, but great improvement has followed galvanization of the cervical sympathetic. I have employed the continuous current from twenty to forty elements (Léclanché). One pole may be placed behind the lower jaw in front of the sterno-mastoid, and the other either at a corresponding point of the opposite side, or at the nape of the neck right or left of the vertebra prominens, or above the sternum at the inner edge of the insertion of the sterno-mastoid.

III. I now turn to a third group of cases, and assume that the indications of mitral regurgitation are manifest *during the evolution of certain fevers*. In the course of typhoid fever, for example, a systolic murmur may be discovered at the apex. There is no history of its existence before the attack, but it has arisen during the course of the disease. The murmur is an evanescent one. To what is it due? The changes are, according to M. Hayem's observations, not in the endocardium nor pericardium, but in the muscle of the heart. In fatal cases the muscular fibres present a granular and fatty degeneration or a special form of vitreous degeneration, the areas of morbid change being disseminated in an irregular manner here and there throughout the cardiac muscle. There are, besides, a multiplication of the muscular nuclei and aggregation of cellular elements. In fact, the disease is a form of myocarditis. It is, I think, sufficiently proven that the murmur occasionally heard at the apex in cases of typhoid is due to regurgitation on account of imperfect apposition of the valves of left or right sides from enfeeblement by disease of the muscular fibres in certain areas of the heart wall. It does not appear that the occurrence of such murmur renders the prognosis more grave; but sudden death, in all probability from myocarditis, may occur in typhoid without any special evidence of direct cardiac impairment previously. Its occurrence, however, should make us watchful, and cases presenting any of the phenomena indicating myocarditis in typhoid should be observed and treated with a view of preventing subsequent dilatation. Analogous myocarditis has been described in variola by MM. Desnos and Huchard, and in severe forms of intermittent fever, as observed in Africa by M. Vallin.

It is obvious that a recognition of the nature of the alteration which produces a mitral regurgitant murmur in the cases we have been considering must have an important bearing on treatment. We need not fear that endocarditis has arisen as a complication, nor have we to debate as to an anti-rheumatic plan of treatment. The indication is to keep the disturbed muscle of the heart as tranquil as possible, and, of course, to promote as good a nutrition as the circumstances will permit.

IV. I now come to the fourth group, and assume that a murmur indicating mitral regurgitation is observed in the subjects of *acute or subacute rheumatism*. Attention has been frequently drawn to the fact that murmurs may arise in the course of evolution of the disease and yet disappear, and patients on convalescence may be supposed to be free from cardiac complication. I have in my former lecture deprecated this as a too hasty conclusion. It may be well to inquire, in the first place, what is the probable nature of these transitory or evanescent murmurs, which are by no means uncommon, for they occur, as the statistics of the London Hospital for 1880 and 1881 show, in about ten per cent. of the cases. Rheumatism is a disease notably attended with anæmia. Is it probable that these bruits are of the nature of those which we have considered to be casually related with anæmia? The evidence collated for me by Dr. Gabbett as to the site of such transient murmurs is, I think, against this view. It is well known that the murmurs noted in connection with anæmia, though sometimes heard at the apex and indicating mitral regurgitation, are far more frequently audible at the base over the site of the pulmonary artery or aorta. Even when heard at the apex they are usually accompanied by other murmurs at the base. In rheumatism, however, the usual site of the evanescent murmur is the apex. The totals for 1881 show as follows: Transient murmurs in mitral area, 15; at base and apex, 7; in aortic area, 5; in pulmonic area, 31. It would appear that a murmur which might suggest an anæmic causation is almost confined to a first attack of rheumatism; after two or more attacks no basic transitory murmurs are recorded. Then, as regards the transient systolic murmur in the mitral area, we may ask whether it may be due to myocarditis. If so, it does not resemble in associated phenomena the murmur observed in typhoid, etc. The peculiar perturbations of rhythm are not recorded, and it would appear probable that if there be myocarditis, it does not occur in disseminated areas, as in typhoid. May it not be that the temporary regurgitation is due to a localized myocarditis developed in the neighborhood of a swollen valve or inflamed endocardium? Thus, though the swollen valve might not be in itself incompetent, a temporary incompetence would be produced by the impairment of the force of the muscle. As the myocarditis subsided the valve would again become competent, but probably in many instances to present a renewed imperfection when the swelling in the course of time has given rise to fibrous change and consequent shrinking. I draw attention to this as a caution as to the expression of any opinion that a valve is sound after a murmur is developed during the early stages and disappearing during the later period of rheumatic fever.

Supposing that mitral regurgitation is left after rheumatic endocarditis, it is well known that compensation may be effected and the health of the patient be preserved for very long periods with no subjective symptom of cardiac unsoundness. The chief factor in inducing such compensation is a conservative hypertrophy of the right ventricle, and the sign of such compensation (supposing the amount of blood regurgitating to be not very small)

is an accentuated second sound over the pulmonary semilunar valves. Supposing that we are satisfied that there is due compensation, medicinal treatment may be entirely unnecessary. I have no doubt that a vast amount of injury has been done to patients by a shaking of the head of the auscultator over the subject of a mitral murmur, who, perhaps, was no worse at the time of examination than he was ten, twenty, or thirty years before, and who might continue uninfluenced for harm by his cardiac complication all his days. He should be cautioned against strain, against exposure, and against irregularities of diet, etc. He may be better occasionally for treatment by iron tonics, cod-liver oil, or strychnine; but any special cardiac treatment is out of place. Not so, however, if there be evidence that compensation is beginning to fail. I will pass in brief review the chief agents which are of service in such cases:—

1. *Digitalis* is *facile princeps* of drugs in the treatment of imperfect compensation. A little over a suitable dose, however, may induce nausea, vomiting, anuria, irregularity of pulse, and, instead of slowing, an enhanced rapidity of heart's action. Whilst a dose which produces favorable result is constant and discoverable in regard to a large majority of patients, in a minority such dose is inconstant, and even unattainable. As regards the preparation used we may have differences of result, and we know that, as in the case of so many vegetable products, the energy of different samples may vary. The pharmaceutical equivalents of the official drugs (P.B.) are a little awkward: one grain of the dried and powdered leaves = one-third of an ounce of the infusion = eight minims of the tincture. Practically, I consider the tincture most reliable, and that usually in small doses five minims to ten minims increased only in exceptional cases, and then occasionally reduced. Next in value I consider the powdered leaves (half a grain to two grains), the combination of which with alkalies I shall hereafter consider. In some cases, even by increasing the dose, no apparent influence appears to be exerted by the drug; then *digitaline*, especially when hypodermically injected, has been observed to give in many cases good results. The *digitaline* hitherto prepared has probably scarcely ever been the pure alkaloid; but it appears likely that by a new process it can be obtained in a state of purity. The usual dose for hypodermic administration is 1-50 grain. For a child of ten years of age with dropsy and great distress from mitral regurgitation, I found, after injection of 1-100 grain of *digitaline* hypodermically injected at intervals of four hours, the pulse-rate reduced by eight per minute after each injection. In this case recovery took place from the urgent symptoms, and the child was sent to a convalescent home. She relapsed, however, and died three months afterwards, when away from our observation. When the right ventricle has dilated so far that there is marked tricuspid regurgitation, the beneficial action of *digitalis* is by no means so decided. Nevertheless (especially when purgatives are also administered), the signs of tricuspid regurgitation may pass away. In other cases no such favorable result attends. In fact, as *a priori* considerations might suggest, any increased power of systole which the *digitalis* may bring about serves the more to force back the blood through the imperfect tricuspid orifice into the venous channels. Yet I have seen good results when the administration of *digitalis* has been combined with abstraction of blood by leeches or cupping.

2. *Belladonna* is, I think, only useful in the treatment of failure of compensation in cases of mitral regurgitation when combined with, or occasionally

substituted for, *digitalis*. *Belladonna*, like *digitalis*, increases the power of systole and raises the arterial tension. As Dr. Lauder Brunton has shown, it paralyzes the cardiac terminals of the vagus and reduces irritability by an anæsthetic effect on the sensory nerves of the heart. Very useful occasionally, it by no means compares with *digitalis* for prolonged employment. The hypodermic injection of 1-50 grain of *digitaline* with 1-80 grain of atropine I have found very satisfactory.

3. *Casca*.—A tincture made from the bark of the ordeal bark of West Africa has been employed as a substitute for *digitalis*. Dr. Lauder Brunton in his *Gulstonian Lectures* for 1877 published the results of elaborate experiments as to its physiological action. In kind this action appears much to resemble that of *digitalis*. Dr. Brunton has said: "Digitalis has hitherto been our great resort in mitral disease, but I think it probable that in *casca* we possess a drug more powerful still; at least its effect upon the arterioles appears to be greater than that of *digitalis*, and it is quite possible that it may succeed in those cases of advanced mitral disease where *digitalis* fails." I have employed the tincture of *casca*, substitutively, for *digitalis*, in a number of cases, but I have not been able to convince myself that it has any more beneficial action in mitral disease.

4. *Caffeine*.—Gubler, Shapter, Leech, Milliken, Brakenridge, Huchard, and others have recorded observations showing the beneficial action of caffeine (or its citrate) in cases of cardiac disease, especially where dropsy is a marked symptom. Some of the cases show very forcibly that a beneficial influence has been exerted by the drug. There are many apparently contradictory data as to the physiological action, but the cardinal points are: that it at first quickens, but soon after slows, the heart's action; that it increases the general arterial tension, and acts in a very pronounced manner as a diuretic in cardiac dropsy. Dr. Brakenridge advises that *digitalis* be administered previously to, or in conjunction with, the citrate of caffeine, and that small doses (three grains) should be employed. M. Huchard, however, recommends that caffeine, and not its citrate, should be used, and that in larger doses (four grains to six grains); it produces diuresis more rapidly than *digitalis*, and has none of its nauseating effect. I have employed citrate of caffeine in substitution for *digitalis* without any marked benefit being manifest; indeed, I have found that in some cases it has induced insomnia. Nevertheless, I consider that the evidence is such that I should certainly employ it in any case where, in cardiac dropsy, a rapid diuretic effect is desirable.

5. *Convallaria majalis*.—This is the well-known lily of the valley, long employed by the Russian peasantry as a remedy for dropsy. Prof. Sée has shown that it has an action much resembling that of *digitalis*. An extract of the whole plant is employed, in doses of from five to eight grains three times a day. In cases of mitral regurgitation with severe symptoms it entirely relieved the cardiac distress and, manifesting a decided diuretic action, removed the dropsy. Professor Sée considers that it may be used in all forms of heart failure, for it has none of the nauseating effects of *digitalis*; nor does it exhaust the contractility of the heart and arteries. I have employed it as a substitute for *digitalis*, and am convinced of its action in promoting a stronger ventricular contraction; but I am not yet convinced of its superiority to *digitalis*.

6. *Morphia*.—The hypodermic injection of morphia, as advocated by Dr. Clifford Allbutt is a most valuable adjunct to the treatment of failure

of compensation in cases of mitral regurgitation. I have found preparations of opium by the mouth generally disagree, but not so when the alkaloid is hypodermically injected. It is often very advantageous to combine the morphia with atropia or digitaline.

V. By no means all the cases which come before us showing mitral regurgitation are to be explained by the modes of causation we have hitherto discussed. In a considerable minority such regurgitation is secondary to continued high tension in the aorta and arteries. It is important for prognosis and treatment to discriminate the cases of *mitral regurgitation due to heightened arterial tension*. In such the apical murmur is usually *post-systolic*, the signs of hypertrophy preponderate, the patient is usually, though not always, of middle or advanced age, the advent of signs has been gradual. Often the arteries may be observed to be tortuous and hard. The most important signs, however, are the discovery either of aortic disease or of accentuation of the aortic second sound with pulse of high tension. Chronic renal disease may be also manifested. When not so complicated great improvement often follows a prolonged treatment by alkalies with iodide of potassium. A carefully regulated diet is most important, and those patients do best, I am convinced, who entirely abstain from alcohol. It is by no means infrequent to find a murmur of regurgitation brought about by such cause wholly to disappear. Their epiphenomena are often to be successfully treated by the administration of nitro-glycerine or the inhalation of nitrite of amyl.

LECTURE III.

MITRAL STENOSIS.

I propose now to consider the morbid conditions associated with a structural change at the left auriculo-ventricular aperture—a change which narrows this outlet and impedes the influx of blood into the left ventricle during the period of diastole. No disorder of function can bring about such a condition as this; the lesions are always organic. We will first glance at the *morbid anatomy* of the affection. If the mitral aperture be viewed from the auricle, it may in many cases be seen that a smooth septum presents itself between the auricle and ventricle, crossed by a narrow slit, almost straight, but inclining to be crescentic. Such a slit may be no larger than a sixpenny-piece or a shirt-button will pass through, and from its appearance the orifice has been termed the “button-hole orifice.” The natural form of the curtains may be entirely lost, their place being occupied by a thick fibrous structure welded at its circumferential attachment with the cords and fleshy columns, which may all be transformed into a dense tendinous mass. In certain cases this fibrous material, as well as the septum, is so much infiltrated with calcareous salts as to make it resemble bone.

Another but less frequent form of obstruction is that in which the mitral orifice, as seen from the auricle, resembles a hollow cone. This is known as the “funnel-mitral;” its ventricular outlet may be so small that it will scarcely admit the point of the little finger. Dr. Hilton Fagge has recorded forty-six examples of the button-hole to one of the funnel form of constriction; Dr. Hayden thirteen of the former to one of the latter; and of my own records of twenty autopsies in cases of mitral stenosis, two only were “funnel mitral.” M. Lancereaux has described a case of mitral stenosis in which, amongst the vegetations which surrounded the thickened orifice, he discovered hard granules, which were shown by chemical tests to

consist of urates. When treated with nitric acid they gave rise to a yellowish product (alloxan), and this, on the addition of ammonia and distilled water, gave the characteristic red color of murexide or purpurate of ammonia. The granules, when dissolved in acetic acid, crystallized in the characteristic rhomboids of uric acid. I draw attention to this observation because it may have an important bearing on the questions of etiology and treatment. I have myself met with a case of mitral stenosis in which there were abundant gouty deposits in the joints, some of which suppurated and gave exit to uratic deposits intermixed with the pus.

It is obvious that the great difficulty created by such alterations as these is the due filling of the ventricle from the auricle. In addition there is, however, in many cases, necessarily a reflux into the auricle at the systole of the ventricle. In proportion as the slit is narrow, the possibility of such reflux is less, and in extreme cases of stenosis it appears probable that no regurgitation is possible. In all cases the main difficulty is the obstruction; that of regurgitation is subsidiary, though frequently coexistent.

It requires only a slight consideration to be convinced that quite a different set of conditions obtains in mitral stenosis to that manifest in mitral regurgitation. Morbid anatomy teaches us that in stenosis the left ventricle is usually not dilated; it has its normal capacity, or is even smaller than natural. We should expect so, for the difficulty is not that the ventricle is habitually overfilled as in regurgitation, but that it is insufficiently supplied owing to the imposed obstruction. Upon the left auricle the consequences of mitral stenosis are very manifest. It is usually not only dilated, but hypertrophied. When dilatation preponderates, it is through an unusual failure of muscular power.

The signs by which we may recognize the lesion of mitral stenosis are as follows:—

First, the *murmur*. This is heard in the neighborhood of the apex of the heart, in the mitral area, but, according to my experience, usually rather to the right of the apex. It occupies the diastolic period—the long pause—usually the concluding portion of it, and then it terminates abruptly with the first sound. It is chiefly Dr. Fauvel, of Paris, and Professor Gairdner, of Glasgow, we have to thank for accurately describing this murmur, and making it available for the practical purposes of diagnosis. The distinction between the murmur indicating mitral stenosis and that indicating mitral regurgitation is to be made partly by the character of the sound and partly by the rhythm. The stenosis murmur is usually of a rattling and rolling character, but its chief characteristic is its abrupt termination; it ends with a sudden stop, as the murmur of regurgitation never does. Even when the murmurs of stenosis and regurgitation are combined, there is usually a spot in the neighborhood of the apex at which the former is heard to stop suddenly, and the systolic murmur to “tail off” from it. The rhythm is determinable by ascertaining the relation to the second sound, and to the impulse of the heart. In approaching the apex from the base, one may be convinced of the commencement of the murmur after the second sound. Near the apex one may hear that the termination of the murmur is with the impulse of the heart as felt upon the chest-wall, or where this cannot be determined the pulsation of the carotid in the neck. Such are very briefly, the chief characteristics of the murmur which is so commonly known as the *presystolic* murmur, that has been considered to be almost if not absolutely pathognomonic of mitral stenosis. I am able to afford the crucial proof of the view that

the causation of the presystolic murmur may be independent of the auricle: first, because in many cases I have observed that though there has been present a prolonged presystolic murmur commencing in the long pause almost immediately after the second sound, cardiographic evidence has shown the auricular systole to occupy its normal position, just anterior to the upstroke indicating the commencement of the ventricular systole; secondly, in a case under my observation, the auricle could have had no share in producing such a murmur, for post-mortem examination showed that not only was the left auricle so dilated that its wall could have exerted no appreciable muscular power, but it was lined by a closely adherent old laminated blood-clot. I consider that it is clearly proven that the so-called presystolic murmur may occur during the diastolic as well as the presystolic period, and that it may be due to the entrance of blood into the ventricle directly diastolic relaxation permits, the blood being urged through the stenosed aperture owing to the tension under which it has been retained in the elastic and distended auricle and the pulmonary veins. The contraction of the auricle may reinforce the murmur and make it loudest just before the ventricular contraction. In a few cases I have found the presystolic murmur closely simulated by the murmur of aortic regurgitation when this is conducted towards the apex, and especially, as is sometimes the case, when it is heard only in the mitral area. Cases have been recorded in which a presystolic murmur has been noted during life, and the autopsy has demonstrated, not mitral stenosis, but aortic regurgitation. Another possible source of error is the existence of pericarditis, when friction may be occasioned by the auricle and cease at the moment of systole. Again, I think most observers will agree that in some cases the presystolic murmur is extremely variable, and may be inaudible during repose, and yet very evident when the patient is made to manifest some slight exertion. Again, it may be absent for considerable periods, and then be readily discoverable. Although, therefore, I consider that in the great majority of cases the presystolic murmur declares with precision the existence of mitral stenosis, it is necessary to consider other signs before committing one's self to a positive opinion.

Another auscultatory sign of great importance in indicating the obstructive lesion is *reduplication*, or a *seeming reduplication*, of the second sound of the heart. This phenomenon is to be noted in at least a third of the cases of mitral stenosis, and only rarely in other conditions. It becomes, therefore, a valuable aid to diagnosis. I have formerly developed before the Society my views as to the mode of production of this seeming reduplication. I will only say here that I believe it to be due, not to any want of synchronism in the closure of the aortic and the pulmonary semilunar valves, but to the normal second sound, followed by another sound due to a sudden tension of the mitral valve itself. The blood, accumulated under pressure in the auricle, rushes through the stenosed aperture as soon as diastolic relaxation permits, and jerks the mitral curtains, or the thickened material which represents them on the ventricular aspect; this gives rise to a sound of tension, which, coming closely after the normal second sound, appears like a reduplication of the latter.

A third sign of importance in establishing the diagnosis of mitral constriction is *thrill*. A thrill at the apex is rarely met with in mitral regurgitation, but very commonly in mitral stenosis. Its rhythm is determinable in like manner with that of the murmur, and if it be presystolic the diagnosis of mitral constriction is assured. I have ob-

served presystolic thrill when there has been no presystolic murmur, and where the condition of stenosis has been indicated by other signs.

A fourth means of differentiation is the determination by percussion of the outline of the heart. If this be done accurately by means of a pleximeter and marked upon the chest wall, with a copying pencil a transfer may readily be taken upon paper and kept for reference. By this method I have shown in some cases (1) an abnormal bulging in the situation of the left auricle; (2) a dilatation of the right cavities and of the pulmonary artery with an absence of dilatation of the left ventricle. The concurrence of these signs has strongly suggested the diagnosis of mitral stenosis when other signs have been obscure. Lastly, a valuable aid to diagnosis may be received from the employment of the sphygmograph and cardiograph.

Very contradictory opinions have been put forth as to the pulse of mitral stenosis. My own observations point strongly to a notable irregularity of the pulse in mitral stenosis; and this in such degree as to afford valuable diagnostic evidence. In mitral regurgitation the pulse is usually regular until compensation is beginning to be imperfect and the right chambers commence to yield. In mitral stenosis, however, irregularity may be evident when compensation is perfect. It is true that many observations may be made with a record of an even and regular pulse; but with repeated observations the peculiarity of mitral stenosis becomes manifest in the trace, a double or even triple pulse is recorded before the base line of the sphygmographic trace is reached. These pulsations are due to repeated systoles, the normal correlation between auricle and ventricle being disturbed. In the later stages, when the right side of the heart commences to fail, irregularities in volume of the pulse may be observed, and in a case where there was great dilatation of the auricle I found the pulse become extremely slow, its rate falling from 80 to 56, and then to an average of 40 per minute. At one time it was 36.

The evidence afforded by the cardiograph when mitral stenosis is suspected is, in my opinion, extremely valuable. The trace enables one to judge of the relative length of systole and diastole. In free mitral regurgitation a very short interval separates the systoles, the duration of the systole, instead of being, as in the normal, less than that of the diastole, is greater. In stenosis, on the other hand, the interval between the systoles may be greatly prolonged. In stenosis the diastolic intervals may be observed to vary greatly in duration; two systoles may occur with no appreciable diastolic interval, and another interval may be abnormally protracted. Much more characteristic, however, is the appearance of a number of vibrations in the diastolic part of the trace—in fact, the vibrations which are heard by the ear as murmur, or felt by the finger as thrill, may be written on the smoked paper by the needle of the cardiograph. I show you many examples. In some it will be seen that the diastolic portion is serrated, and there is no indication of the elevation caused by the auricular systole just before the main upstroke indicating the grasp of the ventricle; in others, vibrations are seen to precede a defined systole of the auricle; in a third set, the auricular systole is well marked, and the sonorous vibrations of murmur, though murmur existed, are not recorded; so I think we have a means of determining, in some measure, the degree of constriction. If such were considerable, it is unlikely that the auricular systole would be readily transmitted and recorded; on the other hand, it is likely that the finely serrated line of vibrations would be produced by the extrusion of blood through the

narrowed aperture. Some of my tracings show in a marked manner the effect of effort in rendering evident vibrations in the diastolic portion which were not visible during repose. By a comparison, too, of the characters of the systolic and diastolic portions, I think we are enabled to obtain some indications whether in combined stenosis and regurgitation the former predominates over the latter, or otherwise, and whether or no hypertrophy preponderates over dilatation of the ventricles.

I pass on now to consider the clinical evidence as to the origin and course of the morbid changes which bring about the obstructive lesion. We are at once met by a body of evidence which shows that mitral stenosis, like mitral regurgitation, has a strong relationship with rheumatism. From the morbid anatomy standpoint, it has been supposed that, at least in some cases, the lesion might have been congenital. Many observations, however, show that the lesions of stenosis which in appearance suggest a congenital causation are met with in cases which are undoubtedly rheumatic. The association with rheumatism is an intimate one. If we inquire, however, as to the degree of such association, we find it decidedly less marked in the case of mitral stenosis than in that of mitral regurgitation. I have found, from statistical inquiries, that stenosis is far less associated with the acute forms of rheumatism than is the regurgitant lesion. Again, it is obvious that repeated attacks of acute rheumatism tend to produce the latter rather than the former. In the cases of children, I have found that it is not the more severe, but the slighter, forms of articular rheumatism which are attended with the obstructive lesion, whilst the opposite is the case as regards the regurgitant. My observations show that the proclivity to the obstructive lesion is in a very marked manner greatest where articular phenomena are not manifest at all. It might be thought that this was evidence rather against the view that rheumatism is a cause of mitral stenosis; but, as I have shown in my former lecture, the advent of endocarditis having the essential characters of that associated with rheumatism may be so insidious that no subjective sign marks its onset, and we have found in many instances that the course of the affection in the non-articular examples, and the morbid changes, as shown by post-mortem examination in the fatal cases, do not differ in any appreciable way from those which are manifest in cases having a distinct history of rheumatic causation. It would therefore appear most probable that the correct conclusion is, not that mitral stenosis is independent of rheumatism, but that it is associated with the less pronounced forms of it—with its insidious, and not (so to speak) with its *explosive*, varieties.

I bring before you examples of (1) presystolic murmur developing insidiously without signs of rheumatism; (2) systolic murmur at apex becoming changed to presystolic murmur; (3) a presystolic murmur developing insidiously, subsequently found to be accompanied by a systolic murmur. The evidence, I consider, tends to show that in a considerable number of cases the origin and course are insidious and gradual. The disease is not independent of rheumatism, but is unaccompanied by pronounced rheumatic phenomena; it is initiated by the form of endocarditis which I sketched in my first lecture as manifested by no subjective sign, accompanied by no prominent symptom, and yet differing in no essential feature from that which occurs in obvious relation with rheumatism. The endocarditis which results in mitral regurgitation is more violent, so to speak, whilst that which initiates stenosis is more protracted, giving rise to a slower formation of fibrous,

quasi-cicatricial tissue that under the even pressure of blood in the auricle tends to form the smooth septum which has erroneously suggested a possible congenital causation.

Not all the cases of mitral stenosis, however, originate in this manner. In some there has been, first, the induction, in association with the phenomena of acute rheumatism, of the lesion of mitral regurgitation; then has occurred probably a slow welding of the curtains, and in the repeated attacks of endocarditis the changes have been slower than those which result in retraction of curtains, cords, and columns to the ventricular wall. By either of these modes produced, it is probable that secondary changes take place in the diseased tissue—under the tension of blood the fibrous septum thickens, for it has to bear the chief strain of the auricular pressure, and not the ventricle, as in the case of mitral regurgitation. In some cases it undergoes calcareous degeneration, and probably in others where gouty signs are manifest it becomes infiltrated with the earthy lithates.

Compensation in cases of pulsal stenosis may be maintained, as in mitral regurgitation, for long periods. It may be even more simple in the former case than in the latter, for it is only a hypertrophy of the right ventricle, and not of both ventricles, that is needed to sustain it. So long therefore as a good nutrition maintains the muscular power of the right ventricle and left auricle, any special methods of treatment of a simple condition of mitral stenosis may be unnecessary. In course of time, however, the right ventricle or left auricle, or both, may begin to fail. Usually it is the former, but I have quoted a case in which it was markedly the latter, and in this I have no doubt the muscle failed on account of the great privations which the patient had undergone. The right chambers dilate on account of the pressure which is maintained within them if the compensating muscular power begins to fail. Then ensue the dyspnoea, the oedema, ascites, etc., which we are familiar with in analogous cases of mitral regurgitation. To restore compensation we may use for the most part similar means to those which we have considered in regard to mitral regurgitation. Even when orthopnoea and dropsy have supervened, I have in many cases found that rest, combined with the administration of nutrients and tonics, with digitalis, have restored the *status quo ut ante* often for a considerable period. Coincidentally with the use of means for increasing muscular power, I consider that small and repeated abstractions of blood are even more valuable in mitral stenosis than in mitral regurgitation. The tension of the right heart may be sensibly relieved even by a leech or two applied over the præcordium.

As regards the special action of digitalis in restoring compensation in cases of mitral stenosis, I am not convinced that this is as markedly proved to be beneficial as in the cases of mitral regurgitation. I have found that in some instances, as shown by the sphygmograph, digitalis has restored regularity, whilst in others it has increased irregularity of pulse. I believe it to be most valuable where stenosis and regurgitation are combined. Where the right ventricle is chiefly at fault, I do not think its good effect is so manifest; where it can induce an efficient systole of both ventricles and coördinate them, then I think it is the more valuable. In failure of the right heart, therefore, in extreme mitral stenosis I look more hopefully to caffeine and to convallaria majalis. M. Sée has recorded instances showing the good effects of the latter in mitral stenosis.

Though the production of the obstructive lesion

is more gradual, I do not think that the prognosis is more favorable than in the case of the regurgitant. We can point to many instances of mitral regurgitation where fair health has been maintained for long periods of years, where compensation is perfect, and where disease of the valves does not progress. Such instances are, I think, less common in stenosis; there is not a like quiescence, and degenerative changes or intercurrent morbid phenomena are more likely to occur.

In mitral stenosis, as well as regurgitation, it is not alone with the simple dynamical problem of restoration of compensation that we have to deal. Certain complications are almost of the essence of the disease, and call for consideration when question arises as to treatment. Such are (1) recurrence of endocarditis, or pericarditis, or both; (2) embolism. I consider that one of the great interfering causes, spoiling the chance of compensation in children and young people, is the occurrence of pericarditis with adhesions. Embolism of some sort is a source of danger, and an element to be considered in a large proportion of cases of valvular disease, especially of mitral stenosis. Clinical examples are brought forward showing the occurrence of this complication (1) on the venous, and (2) on the arterial sides of the circulation.

Embolism of a branch or twig of the pulmonary artery is a very common cause of the bronchopneumonia observed in mitral diseases, a characteristic feature of which is hæmoptysis. The occurrence of such symptoms in a case which has hitherto been questioned tells us that compensation is disturbed, that circulation is sluggish in the right chambers, and we are called on to strengthen the ventricles by cardiac tonics as well as to maintain rest. In all such cases it is desirable to restore the tendency to coagulation of the blood by the administration of alkalies, especially ammonia.

I bring forward also examples where arterial embolism has been the first clinical sign of mitral stenosis, the embolism giving rise to hemiplegia, hemichorea, epilepsy, etc. In cases under treatment for cardiac diseases the one sign which I have found to indicate the probability of the occurrence of embolism is a sudden rise of the temperature of the body. In all such cases the most perfect rest should be enjoined. I think also that an attempt should be made to render the deposit of fibrin less likely by the administration of ammonia or other alkalies. The induced phenomena, of course, call for treatment according to the organ or situation in which infarction occurs.

Clinical Lecture

ON

EXPLORATION OF THE BLADDER BY PERINEAL SECTION OF THE URETHRA,

AS A MEANS OF DIAGNOSING OBSCURE VESICAL DISEASES, AND OF REMOVING THE CAUSE WHEN IT CONSISTS OF TUMOUR, ENCISTED CALCULUS, ETC.

Delivered at University College Hospital on Jan. 29th, 1883,

By Sir HENRY THOMPSON,

Surgeon Extraordinary to His Majesty the King of the Belgians,
Consulting Surgeon and Emeritus Professor of Clinical
Surgery to University College Hospital, etc., etc.

GENTLEMEN—I have many a time in this place discussed the ordinary affections of the urinary passages, and endeavored to illustrate before you

the best methods of dealing with them. To-day I propose to call your attention to the unusual and obscure cases which sometimes occur, and to a new mode of investigating them, which is, I believe, destined to be extremely valuable. You are to understand clearly at the outset, that the plan I propose is not to be resorted to with anything like frequency in urinary diseases, nor, indeed, is it to be thought of in any single instance until we have failed, after prolonged and intelligent inquiry, by the means generally adopted to ascertain the nature of these affections. But I suppose that all of us, including even those who have enjoyed a very large experience, must confess that now and then a case is presented, manifesting severe and obstinate symptoms of urinary disease, of which, although a careful examination has been made, establishing all the facts which an exhaustive inquiry can elicit, we are unable to make a rational diagnosis, or materially check the progress of the complaint. But in the great majority of cases such an investigation enables us, at all events, to decide in which of the three principal divisions of the urinary organs the disease is chiefly situated—whether in the vesical, the ante-vesical, or the post-vesical region. I say “chiefly,” because morbid changes may exert an influence or extend beyond the limits of a single division. Let me just say here, that in the “vesical division” I intend, of course, to include every pathological condition which can affect the bladder, that the post-vesical division embraces all affections of the ureters and kidneys, while the ante-vesical division denotes all diseases to which the prostate and urethra are liable.

Such a classification is a natural one, and it is from a practical point of view desirable to determine at the outset of the inquiry this question of locality.

It will be obvious to every student in regard to the last-named, or ante-vesical, group, that the ability to make a physical examination of the urethra and prostate without difficulty, should leave little ground for doubt as to the diagnosis or the treatment of any affection of that region, although we may not be able always to affirm or deny the presence of some post-vesical affection also, in addition to the more obvious disease.

By way of indicating a typical example of the cases which are presented for careful investigation, because the affection is obscure, let me suppose a patient before us, who may belong to either sex, and who may be an adult of any age, and of whom the following particulars are affirmed.

He or she is the subject of unduly frequent micturition, both by day and night; the act itself is almost always painful, while pain, or at least uneasiness, more or less constant, is felt about the loins or pelvis. Then hæmaturia occurs with frequency, and is more considerable on some days than on others; but besides blood, the urine contains also pus and mucus. The signs and symptoms named have existed for a considerable period of time, and, although varying in intensity from week to week, have notably increased during the last few months. It is manifest also that the condition is not the mere sequel of an attack of acute cystitis, or to local poisoning as by gonorrhœa or the like; nor is it the result of any mechanical injury.

The method of inquiry best calculated to elicit ascertainable facts in such a case, consists in solving the following questions, and these are placed in the order in which it is generally best to determine them.

1. Has the urethra a sufficient calibre? To be ascertained by means of the bougie.

2. Does the patient empty the bladder by his natural efforts? To be ascertained by passing a catheter immediately after the patient's natural act of micturition.

3. Is any enlargement of the parts, either prostatic or vesical, notable on making rectal examination? seeking, of course, either the full, rounded contour of the hypertrophied prostate, or the hard irregular nodules of a cancerous growth.

4. Can the presence of foreign body in the bladder be demonstrated by the sound, or can any other abnormal condition be thus detected?

5. Are the signs of renal disease present in the form of constitutional albuminuria, habitual exfoliation of casts, of tubes, etc., or are there grounds for suspecting the presence of a calculus in the kidney, or possibly in the ureter, or of an abscess or tumour there?

Now, the whole of these queries may be answered in a sense favorable to the patient; in other words, no evidence of the presence of organic disease may be elicited by any one of these inquiries, nothing, indeed, discovered beyond the simple facts which constitute the group of signs and symptoms complained of, and which are of themselves insufficient to determine the nature or the locality of the disease. Let me, however, remark here that observation of the urine from time to time sometimes reveals a sign of great importance not yet mentioned—viz., the presence in it of small fragments of tissue which, under the microscope, show structure resembling that of the fibromatous or villous growths which occasionally spring from the internal coat of the bladder. There is another sign of great importance, second only in that regard to the presence of débris. The stream of urine issuing as usual of the normal tint sometimes changes to a florid red before ceasing to flow. Such an occurrence ought to be verified as fact by more than one observation. When it does occur the bleeding is always vesical or prostatic; when the blood is not only florid but rather plentiful, tumour of some kind is almost always present. Such evidence is highly significant when associated with the history and symptoms just described.

The conditions thus sketched, however, are not those of a common case. In the great majority of our patients a moderately careful and intelligent examination places beyond doubt by adequate demonstration the nature of the disease which produces the symptom in question. Now, it is for the few exceptional cases, and these are always very important ones, with a history of hæmaturia manifestly not renal, already referred to, with a history of treatment, too, by internal remedies reputed to be styptic, and beyond this chiefly watched for the development of more advanced symptoms, but with no purpose of surgical interference—it is for these cases, I say, that I propose to take a new and decided action. And I desire very strongly to submit also that such action ought not to be postponed until a stage has arrived when the operation of diagnosing and efficiently treating the disease may probably be accompanied by serious danger to life. And on this ground especially, that if the cause of the hæmaturia be tumour or growth of any kind the issue will certainly be fatal, unless the disease can be removed by operation.

The first and the essential step in the method I propose consists in examining the entire internal surface of the bladder with the finger, by which means we can easily recognize the presence of any tumour, large or small, or even of an irregularity or roughness in the surface of the lining membrane, or the existence of any calculus lodged

in a sac or sinus, or otherwise hidden from the researches of an ordinary sound passed by the usual route through the urethra. Of course it must be sufficiently obvious to everyone that the ability to do this easily, effectively, and safely, offers a valuable addition to the means ordinarily employed, for the most difficult and hitherto intractable cases of urinary disease which come before us.

But you naturally ask me, Is it possible that such an examination can be effected on the terms just named, that is, with ease, efficiency, and safety? I have no hesitation in answering you in the affirmative.

I am, however, quite free to confess that a few years ago I should have been unable to make such a reply, and that it has only been after some unusual experiences which have fallen to my lot during the last few years, that I have satisfied myself that we can, without difficulty, examine the entire surface of the bladder with the tip of the finger.

Certainly before the discovery of anæsthesia the proceeding would have been impossible. But mere anæsthesia is insufficient: it is essential, in the first place, that the influence of the anæsthetic agent should be carried far enough to ensure complete relaxation of the voluntary muscles, so that their tension should not impede any action of the operator. This condition being fulfilled, it is, in the second place, necessary that the tip of the index finger should be placed just within the internal meatus at the neck of the bladder. Next, it is to be remembered that when the bladder is empty—that is, not distended by urine or by a calculus—the cavity presented for exploration is a small flaccid bag, sometimes merely a cul-de-sac, every portion of which is situate at a short distance from the finger placed in the position just described. Lastly, if the finger of the operator's left hand be maintained in that position, while he makes firm suprapubic pressure with his right hand, I maintain that there is no difficulty in bringing every portion of the internal surface of the bladder, successively, into close contact with the tip of the left index-finger; a contact which enables him at once to estimate correctly the condition of the interior, in relation to every important particular necessary to be ascertained.

Before considering the best mode of performing the simple operation which enables this exploration to be effected, I will anticipate an objection which may very naturally arise in some minds—viz., that we are not always able to reach the neck of the bladder with the tip of the finger when the incisions for removing a stone by the lateral operation have been completed. Hence it is notorious that a long and flexible index-finger is regarded as an important element in the making of an able lithotomist; yet, although possessed of it, he may still be unable to reach the point in question, in a few exceptional cases.

To this I reply, that there are few bladders indeed into the neck of which, even when the prostate is large, a finger of ordinary length may not be introduced, if carried straight in from the centre of the perineum, which is the shortest route from the surface. But, in addition to this, I refer to the fact which I have verified by experience—viz., that firm suprapubic pressure made by the right hand of the operator, or aided by an assistant if necessary, will accomplish the object, even in an exceptionally deep perineum, if the index-finger is firmly pressed up from the perineum to meet the other hand. Of course, when large outgrowth of the prostate is present, occupying the neck and cavity of the bladder, it may be impossible to carry the finger to the point desired; but then it is to be

remembered that in such circumstances there is no need to make incisions in order to explore the internal surface of the bladder, the case not being an obscure one, but, on the contrary, quite unmistakable.

Let us now consider the manner of operating, so as to place the tip of the left index within the neck of the bladder. The first object to be attained is the opening of the urethra at or about the membranous portion, by the simplest and shortest route from the surface of the perineum, making a passage only sufficing to admit with ease the entry of the forefinger and no more. There can be no doubt that a vertical median incision—that is, one made in the line of the raphe—will fulfil this indication better than any other. In this situation the prominence which is formed by the bended knuckles of the operator, when introducing as far as possible the index-finger, lies in the hollow equidistant between the two nates, and presses directly towards the centre of the bladder. Any incision made right or left of the median line must of necessity lead obliquely to the centre, and be therefore a longer line, because it commences at a point on the external surface more distant from the neck of the bladder than is the raphe of the perineum. Accordingly I prefer, and always employ, a vertical incision in the centre of the perineum, carried straight to the urethra, aiming at the point close behind the bulb, a procedure which as far as the incisions are concerned has been practiced by surgeons for centuries to relieve stricture, retention, etc., objects, however, altogether differing from that for which I have employed it, and which is the subject of our consideration here.

The patient then is to be placed in the ordinary position for lithotomy, a rather short, well-curved staff, with deep median groove is passed into the bladder. The operator enters the point of a long, straight bistoury about three-quarters of an inch above the anus, and makes a vertical incision upwards of the skin, not more than an inch or an inch and a quarter in length. He then carries inward the knife deeply, nearly parallel with the rectum, in which the left index should be placed, to inform the operator of the relative positions of the blade and the bowel, until the point reaches the groove of the staff about the membranous portion of the urethra. He is next to incise the tissues covering the groove for about half an inch; the left index is then to be introduced into the wound, the nail insinuated into the groove, then slowly into the urethra beyond, gradually dilating it. When the finger is fairly lodged in the prostatic urethra, the staff is withdrawn, and the finger is pressed firmly onwards until it enters the neck of the bladder; and it should now be felt to fill, or nearly so, the entire wound, and it does so if the incisions have been made as directed. As a rule very little bleeding results. The operator now, maintaining his finger in the situation described, should rise from his seat to the standing position, place his right hand on the patient's abdomen, directly above the pubic symphysis, and make firm pressure into the pelvic cavity. He will soon recognize the end of the left index-finger, and by concerted movements of the two hands he may, as I have already said, examine with ease the upper surface of the bladder, and explore the lateral walls, the fundus, and trigone; the latter more completely, if necessary, by placing the other index-finger in the rectum.

You will observe that the procedure thus described is simply a limited external urethrotomy, not "cystotomy," as when incision of the neck of the bladder has also been made; much less is it "lithotomy" in any form. The incision involves

only a small portion of the urethra anterior to the prostate and neck of the bladder, which are left perfect and intact throughout. Hence its result is to enable the male bladder to be examined almost as readily as that of the female in its natural condition, an approximation to which is attained by the operation; and in the female, as you know, dilatation of the urethra alone suffices to permit the finger to enter the viscous and explore it.

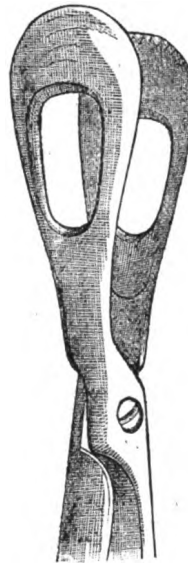

Fig. 1.
The forceps for removing
tumours (No. 1).

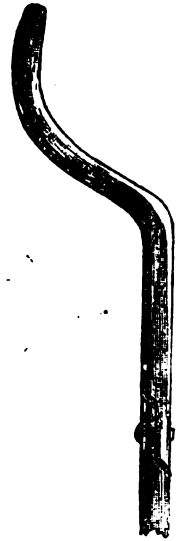

Fig. 2.
Curved forceps (No. 2), for
tumours springing from
the side of the bladder.

We will now suppose the result of such an exploration to have been that the operator's finger recognizes the presence of a soft protruding mass or flocculent growth springing from some part of the bladder. If brought within reach of the finger by supra-pubic pressure, it is easy to verify the nature of the peduncle, whether it be narrow or broad, together with any other physical characters which are obvious to the touch. The operator will next introduce a forceps, the extremities of which meet by broad roughened edges, so that they nip off, without cutting, the greater part of the salient portions of the tumour. Those that I have designed for the purpose are shown at Fig. 1. The extremity of each blade meets its fellow by a margin of about an inch long and about one-sixteenth of an inch broad, and these are indented so as to effect a separation of the morbid tissue, with as little chance of producing hæmorrhage as possible. With this instrument the greater portion of almost all growths can be removed. But I soon met with a case in which a small growth protruded close to the neck of the bladder, and although with the forceps described I took away the protruding portions from the other aspects of the bladder, I failed with this instrument to seize the small one close to the neck. For this I designed another forceps (No. 2, Fig. 2). It will be readily seen that by means of this instrument it is easy to remove any growth in the situation described, and both forms should be at hand when making exploration of the bladder. Since the occurrence referred to I have operated in three other cases of large vesical

Fig. 3.

The same forceps, or No. 2. Front view, showing divergence of blades by joint, to prevent nipping of the soft parts at neck of the bladder when closed.

tumour in the male, springing from the left side of the bladder not far from the neck. These I removed chiefly with the curved forceps (No. 2), the other forceps being almost inapplicable (see Figs. 2, 3). Perhaps there are circumstances in which an *écraseur* may be a more efficient instrument than the forceps for removing a growth; this, however, I venture to doubt. In order to adjust the cord or wire, more room is necessary for manipulation than the incisions described will furnish. It is better to keep these within narrow limits when it is possible, and such have sufficed me for the complete removal by the forceps of a very large tumour. The forceps and the finger are of course to be employed alternately, the one to define clearly what the other is to lay hold of; for I have never found it necessary to make a wound large enough for both finger and forceps to pass in company. But the *écraseur* would require an accompanying finger, and more space must accordingly be secured for their joint action, which I object to because it is certainly undesirable to make extensive incisions. In the female the *écraseur* can be more easily managed because room is

more readily acquired without section. After the chief portions of tumour have been removed from the bladder, it should be washed out with a current of cool water, by means of a syringe and tube through the wound, after which a large vulcanized catheter is to be introduced, so that about half an inch lies within the bladder, and in this position tied by stout bobbin to a bandage round the patient's waist. The other end protrudes some five or six inches, and is placed within a bottle, adjusted to receive the contents of the bladder. Hemorrhage is usually free during twenty-four to forty-eight hours, and then slowly ceases; pain is sometimes but not always severe, and should be controlled when necessary by a morphia injection. The tube should remain from five to eight days and then be removed, when the wound rapidly heals and all the urine soon passes by the natural channel.

A brief *résumé* of some fifteen or sixteen cases, six of which are those of vesical tumour removed in the manner described, will be given on another page.

Hunterian Oration

DELIVERED AT THE

ROYAL COLLEGE OF SURGEONS OF
ENGLAND

On February 14th, 1883,

By T. SPENCER WELLS,
President of the College.

MR. VICE-PRESIDENT, MY LORDS, AND GENTLEMEN—
Just seventy years ago, Matthew Baillie and Everard Home, being, to use their own words, "desirous of showing a lasting mark of respect to

the memory of the late Mr. John Hunter, which shall at the same time express the very high sense they entertain of the very liberal conduct of the Royal College of Surgeons in supporting and preserving the Hunterian Collection," agreed with Sir William Blizard and Mr. Cline to endow "an annual oration, to be called the Hunterian Oration, which shall be read or delivered in the theatre of the said College on the 14th day of February in each and every year (being the birthday of John Hunter)." They devised that such oration "shall be expressive of the merits in comparative anatomy, physiology, and surgery, not only of the said Mr. Hunter, but also of all such persons as are or shall be from time to time deceased, whose labors have contributed to the improvement or extension of chirurgical science. After the first oration in 1814, one was delivered every year until 1849. Since that year it has been biennial, and the indefinite phrase "from time to time deceased" has been interpreted as applicable to the Fellows and Members and other distinguished men who have died since the delivery of the previous oration. This custom I shall follow; and before alluding to any other subject, I will endeavor to bring before you some account, necessarily very brief, of a few of the men who have died since February, 1881, "whose labors have contributed to the improvement or extension of chirurgical science."

Were I to attempt to do more than make a passing allusion to such men as Schwann and Bischoff and Darwin and Rolleston, and include comparative anatomy and physiology in the term "chirurgical science"—which in the home of the Hunterian Museum I should almost be bound to do—the short space of one hour would be so fully taken up as to exclude any other subject. And even if I were to include some of our countrymen who have rather advanced the medical department of chirurgical science, and allude to such veterans as Christison and Billing, or Alderson, or Watson, whose loss is so recent, and to whom personally I shall always be grateful for kind encouragement in the earlier years of my practice in London; or to our Scotch brethren, as Pirrie and Spence; or Thompson, of Lisburn, who did the first ovariectomy in Ireland; or McClintock, a leader among our Dublin brethren—any notice must be so brief as to be useless. Still more so were I to include those of our brethren abroad or in America, like Pirogoff, Busch, Hueter, Davaine, Atlee, who now "rest from their labors," and whose "works follow them." I am compelled therefore—not from want of respect or appreciation of such men, but simply from want of time—to limit my remarks to those Fellows and Members of this College who have died since Mr. Holden's eloquent oration was delivered here two years ago.

Three hundred and sixty-seven Members and Fellows are included in this death-roll of only two years. A hundred years ago, in 1783, when Hunter had just bought the house in Leicester-square, which in its altered form of Alhambra was burnt down last year, the Members of this College numbered 835. In a hundred years we have increased in number more than twenty-fold, for we have now 16,093 Members and 1,186 Fellows—a total of 17,279 men associated in our work. In the two years which have passed since the last Hunterian Oration, 367 of the Associates have died. The average age of the Fellows was about sixty-six years, and of the Members fifty-seven years. One Fellow and four Members attained the age of ninety years and upwards, and the other thirteen Fellows and twenty Members eighty years and upwards. A few Members died within five years of obtaining their diplomas, and we lament the loss of one Fellow who was only admitted last year.

Two of our deceased Fellows—Luke and South—had attained the highest position in our College. Both were members of Council, both examiners, both had been President twice, and both had been teachers of surgery in large metropolitan hospitals.

Mr. Luke was twice President of this College—in 1853 and 1862. He delivered the Hunterian Oration in 1852. For many years he was one of the examiners, and he was connected with the London Hospital from 1816, as a pupil, till his death at the age of eighty-two, when, after having long retired from private practice, he held the office of consulting surgeon. He attended the lectures of Abernethy and Astley Cooper, and was one of the personal links connecting these great masters of our art with the surgeons of our time. Luke's work as hospital surgeon and as teacher certainly contributed to the advance of surgery in his time. In his operation for femoral hernia, by small incision and division of the stricture without opening the sac, his success was very remarkable. In his Hunterian Oration Mr. Luke refers to a letter of Hunter's urging upon this College the establishment of a library, which he "would consider one of the happiest wants of his life," as a proof that he regretted his own deficient early education; and Mr. Luke strongly insisted upon the necessity of a good general education for all medical men, and upon the study, specially of French and German, and he spoke with great satisfaction of the examinations in the classics recently instituted by the Council of this College. Turning to the study of Hunter's character as an example to ourselves, he noted the "perfect honesty and integrity of all his scientific and professional acts," his indifference to money—except as enabling him to promote his favorite objects—his beneficence, his wonderful industry, and his careful subjection of all his doctrines to the test of fact or experiment.

South was one of the last surviving relics of the staff of the then united hospitals of Guy's and St. Thomas's; apprenticed to the younger Cline of St. Thomas's, and after very many years' service as assistant-surgeon there, succeeding too late in life to the full surgeoncy. He was a member of our Council from 1841 to 1871; was an examiner for many years; was Arris and Gale Professor; delivered the Hunterian Oration in 1844; and twice, in 1851 and 1860, was honored by the highest distinction his colleagues on the Council could bestow. His works are translations of Otto's well-known Compendium of Anatomy and of Chelius's Surgery, which he greatly enriched by his own notes. His text-book on the Bones and his Household Surgery have both done useful service. When Frank Buckland discovered the coffin of John Hunter in St. Martin's vault, it was owing to the exertions of South that the body was removed to Westminster Abbey, and the inscription on the tablet which has been placed over the grave in the Abbey was written by South. For many years he had been engaged on a history of this College and of the Barber-Surgeons. His widow has permitted me to read the manuscript volumes—most beautiful specimens of neat and distinct hand writing, and very extraordinary evidence of industrious research. One extract from these volumes I may now use as illustrating the advancement of the College since Hunter's time.

A former President—then styled Master of the Corporation, Mr. Gunning—wrote as follows, on retiring in July, 1790, from the office of Master. John Hunter was one those present when these remarks of the Master were read. After some complaints of the imperfect way in which the College books were kept, and the unnecessary expenditure

on dinners, he said:—"Your theatre is without lectures; your library room, without books, is converted into an office for your clerk; and your committee-room has become an eating parlor. . . . If, gentlemen, you make no better use of the hall than what you have already done, you had better sell it. . . . I am sorry to observe that you have instituted lectures neither in Surgery, nor indeed in Anatomy of any degree of importance, nor have you held out any gratification or reward for rising merit."

Now our library contains about 39,000 volumes, and every year becomes a more complete library of medicine and the auxiliary sciences. Our museum is our chief possession, the most complete of its kind in the world, and the offices of assistant-conservator are valued as rewards to rising merit. Our hall is not only used for the lectures of Flower and Parker, Power and Eve, and of a succession of our leading practitioners, but for the examinations of the young men who will become the surgeons of the future. The Council has already taken the first step for providing additional accommodation for the examinations by securing the services of one of the greatest architects of our time—Mr. Waterhouse—to report upon different plans, which will have to be carefully considered. I am also hopeful that, by a judicious outlay of part of our accumulated funds—assisted, perhaps, by contributions or legacies—we may supply what is now felt to be a great want—I mean such a complete central pathological laboratory as may assist the men who are leading the advance of experimental physiology and pathology. Dr. Ogston's work at Aberdeen, on micrococci poisoning, has already proved how very useful such a laboratory may be, and more than justifies the most sanguine hopes of the good to be expected from the endowment of a chair of Pathology in the Northern University by the munificence of my predecessor in the Presidency of this College, Sir Erasmus Wilson.

George Gulliver, who died last year in his seventy-eighth year, was a pupil of Abernethy, dresser to Lawrence, surgeon in the Guards, one of the first Fellows of the College under the new charter—elected "in recognition purely of scientific merit"—for twelve years a member of our Council, and Hunterian Professor of Comparative Anatomy and Physiology. In 1863 he delivered the Hunterian Oration in this place, warmly criticising some who had said that the material for these orations is "nearly exhausted." He maintained that "there is perennial interest and instruction in reviewing the works of a man of genius, in the now steady and now fitful lights and shadows of advancing science, and he warmly upheld, against what he believed to be unfounded claims of French and German physiologists, the just merits of the British school of physiology, instancing the labors of Hunter and his disciples, especially of Hewson, who "fairly entering that prolific field of cells and endosmosis which was left utterly forgotten and barren for upwards of half a century afterwards, until new minds, with the aid of better instruments, found in it such a variety of rich fruits, and confirmed so many of his long-neglected conclusions." In one of Gulliver's lectures he asserted that a moderate quantity of beer may promote the formation of a chief product of digestion—the chyle. His illustrations of the molecular base of the chyle, of the intimate structure of tubercle, of the softening of fibrine, and his investigations into fatty degeneration of tissues and their relation with arterial changes and apoplexy, were all in advance of the pathology of his day. He argued that the modern "protoplasm" is but a synonym of the old "coagulable lymph," and that a delicate shut sac

might be formed by coagulation of fibrine without any cell agency. His demonstrations that the red blood-corpuscles in the mammalia are non-nucleated, while in the oviparous vertebrates they are nucleated, was a distinct addition to the knowledge of the age; and his experiments upon the conditions under which fractures of the patella are united by bone or only by ligament, as well as his observations upon shortening of the neck of the thigh bone in young persons, were important additions to surgical diagnosis and pathology. Gulliver's life affords another proof that the career of an army surgeon is far from being unfavorable to the cultivation of science. His son, now assistant-physician at St. Thomas's, has already shown that he is worthily following in the path which earned honor for his father.

The name of George Critchett recalls to many who hear me meetings for several years at our Council table, and his pleasant companionship at many less serious gatherings; and it would be difficult to name one whose loss has been more sincerely regretted. His life and work are remarkably illustrative of the recent extraordinary progress of ophthalmology in this country. It has been said of him that his career commenced in the "pre-scientific period of ophthalmology," but it must not be forgotten that the foundations for the most important of the advances of the German school were laid in England by Hunter, in ground prepared by Isaac Newton and Thomas Young. The anatomy of the eye was well known before Hunter's time; and Haller and Hunter, with Newton and Young, had done much to increase our knowledge of the physiology of vision. Daviel's extraction of cataract, Cheselden's iridotomy, and the treatment of diseases of the lacrymal sac were already proofs of great progress. But it was not until after the beginning of this century that well-educated surgeons in any country devoted themselves to the study of diseases of the eye. Hunter's papers on the use of the oblique muscles, on the color of the pigmentum of the eye in different animals, and his investigations into the structure of the crystalline lens are proofs of his interest in the subject. The foundation of special hospitals in London in 1808 and 1810, followed soon after in other large towns and in Scotland and Ireland, and the works of such great surgeons as Travers, Lawrence, Guthrie, and Tyrrell—of such an anatomist as Jacob, and such an oculist as Mackenzie—did much to increase the general knowledge of diseases of the eye. In Germany, until about thirty years ago, the school of Vienna occupied the most important position. Then the school of Berlin entered upon the path which has led to as great, as rapid, as extraordinary a progress as ever has been recorded in the history of any other branch of medicine, equalled only by the advance gained during a still more recent period in abdominal surgery, surgical gynecology, and the use of antiseptics. It was in 1851 that the great physiologist, Helmholtz, invented the ophthalmoscope, and thus enabled us to investigate some diseases of the eye which before were completely hidden in darkness. Just at this time Albrecht von Graefe began his brilliant but short career, and in twenty years he worked out all the most difficult and complicated questions in ophthalmology for the aid of the practical surgeon. Graefe called to his side many able men to assist in his great work. Heinrich Müller worked out the microscopical and pathological anatomy of the eye; Donders the affections of refraction and accommodation; and one distinguished German, who joined this College after a brilliant career in Berlin and Paris—Liebreich—devoted himself mainly to the study and teaching of the ophthalmoscope. I well remember,

when in 1853 I brought from Berlin almost the first ophthalmoscope which was tried in this country, with what delight Critchett watched its earliest trials. When some called it a "toy," and others feared its possible dangers to a sensitive retina, Critchett eagerly tested its utility. He, and a fellow-workman happily still among us, beloved by many and honored by all, who had done much to increase knowledge of the "parts concerned in the operations on the eye," and whose microscopical researches had greatly increased our knowledge of ocular histology (even to our visitors I need not name Bowman), side by side with generous rivalry and throughout a long and useful career, either by improvements in practice or by clinical teaching and additions to our literature, greatly assisted in the recent progress of the science and art of ophthalmic surgery. How much of this progress is due to the teaching and example of Critchett, at Moorfields and the Middlesex Hospital, it is perhaps difficult to say; but it is certain that no one could see him operate without admiration or without some desire to be able to imitate his perfect coolness, his delicate touch, and his exact precision; while all might learn how a successful operator, by attention to every detail which can influence the result, deserves and obtains his success and his reputation. A junior colleague, Soelberg Wells, had studied in Berlin under Graefe, and his Handbook became a valuable guide for our students. His faithful and fertile work at Moorfields and King's College will not be forgotten in the annals of those institutions. Liebreich will be remembered by his enthusiastic and successful work for ten years at St. Thomas's, and the translation of his "Atlas of Ophthalmology" (equally distinguished by artistic skill as by a faithful and trustworthy interpretation of intra-ocular changes) will always be valued as a notable contribution to the literature of modern ophthalmology. Our public schoolrooms have also been greatly improved by the seats and desks suggested by his endeavor to remove some prevalent causes of defective vision. He now enjoys artistic leisure in a sunnier clime. George Critchett's labors are over, but his son remains, and we may rejoice in the continued accession of able workers in this special field. And while we have so many special hospitals, and eye departments in so many general hospitals, and such men as work in all, there is no fear for the future of ophthalmic surgery in the country where its foundations were laid, in optics by Newton, and in physiology by Hunter.

Probably no man in the whole world, during the last twenty or thirty years, has done so much with his own hands to prevent or relieve severe pain as Joseph Clover. As an administrator of chloroform, or of some other anæsthetic, his services were in almost constant demand. For many years resident in University College Hospital, then extensively occupied in general practice, he became so well known for his careful and precise mode of administering narcotic vapors or gas, that little time was left him for other pursuits. In some respects, although he supplied a real want in daily practice, this limitation of his work is to be regretted; for the valuable improvements he made in several surgical instruments, especially in the double-current exhausting syringe, so useful in lithotripsy, afterwards improved by Bigelow, prove that with less delicate health and more leisure, his many friends would have been able to record more numerous and enduring memorials of the life-work of a singularly industrious man. Now they must be content with thinking

On that best portion of a good man's life,
His little, nameless, unremembered acts
Of kindness and of love.

I should hardly do more than mention the name of Dr. Peacock, though one of our members, as he was so purely devoted to the practice of a physician, if he had not been one of our examiners. And now I can do little more, for want of time, than allude to his valuable gift to our museum, in recognition of which, in 1876, he received the honorary gold medal of the College. He died when visiting St. Thomas's Hospital, in a ward which had been under his own charge during his years of active work and teaching.

Few men were better known in our Medical Societies, from ten to thirty or forty years ago, than Edwards Crisp. His Jacksonian Prize Essay on the Structure, Diseases, and Injuries of the Blood-vessels remains a sufficient proof of the industry and attainments of a very active man. In his later years he spent much time in investigating diseases of the lower animals, and the natural history of parasites. He obtained the Astley Cooper Prize for his essay on the Structure and Use of the Thyroid Gland; a second time the Jacksonian Prize, on Intestinal Obstructions—besides others on Croup and Diphtheria, and Disease in Lambs. He first demonstrated the existence of valves in the splenic vein. He is said to have accumulated a museum of comparative and pathological anatomy exceeding 5,000 specimens. He was a remarkable instance of a man who, busily employed in the daily work of a large general practice, also took an active part in medical politics, while assisting usefully in the advance of zoological science and human and comparative pathology.

Still, without passing from our London brethren, I have to record the loss of five veterans:—Griffith, of Gower-street, died at the age of ninety, after having honorably carried on a very large general practice for more than sixty years.

George Macilwain, so well known at the Medical Societies and the Royal Institution for so many years, who wrote the Life of Abernethy, and a thoughtful book entitled "Medicine and Surgery one Inductive Science," reached the age of eighty-five.

Francis Godrich, after practicing at Brompton for sixty years, died at the age of eighty-five. He was one of the founders of the Medical Benevolent College, and he took a leading part in all the improvements and charities of the districts in which he practiced. He greatly assisted Mr. Wakley in his successful conduct of the Medical Witnesses Bill through the House of Commons.

Another octogenarian, John Merriman, was one of a very old medical family. Samuel Merriman the elder attended the lectures of William Hunter, and practiced in London all through John Hunter's career. Having attended 12,000 cases of labour, he took for his motto, "Terar dura prosum," which the family have retained ever since. He died in 1818, aged eighty-six. His nephew, the second Samuel Merriman, author of "Difficult Parturition," died in 1852. These two were uncle and cousin of John Merriman, who began practice in Kensington the year after the death of John Hunter. He was the father of the second John Merriman, whose death I have just referred to. He was attached to the household of the Duchess of Kent, and of our Queen, attended the Princess Sophia, was consulted by the Prince Consort, and received many proofs of the gratitude of these royal persons. He carried with him into pleasant retirement the good wishes of all classes in the "old Court suburb," and he is succeeded by a son and grandson who worthily maintain the traditions of the name they bear.

Frederick Toulmin died in his eighty-fifth year only ten days ago. He had practiced for nearly fifty years in Clapton, where he and his brother

succeeded their father. He was a kindly, genial man, a charming companion, and his anecdotes of the leaders of the profession in his early days were many and very interesting. Mr. Toulmin's great-grandfather was a surgeon. His brother and his nephew are the fourth and fifth in direct family succession in the profession during a period of more than 150 years. He was a dresser under Sir Astley Cooper, and the testimonial which Sir Astley gave him, when a candidate for a dispensary surgeoncy, was so gratifying to him, and is so characteristic of the great surgeon, that I venture to read it here. Sir Astley wrote: "When I look around me and observe the number that I have had a share in educating, I find no individual to whom I am more sincerely attached than to Frederick Toulmin. If I be asked the reason of this, my answer will be that his knowledge in all the branches of his profession is most extensive, and his character as a man the most amiable. My best wishes will ever accompany him. His prosperity will always be next my heart. Astley Cooper."

Among the general practitioners around London I may mention Stephen Alford, of Hampstead, who took an active and useful part in the attempts made for several years past to protect and reform habitual drunkards; Hemming, who worked hard at diseases of the ear; and Duke, of Clapham, who after more than forty years' work in very varied and large practice, and continual struggles with parochial authorities when fighting the cause of the sick poor, has left the best of all legacies to the many sons who follow their fathers' profession—the "good name" which is "better than riches." It is to such men as these that Johnson's portrait of his friend Levett would apply:—

When fainting Nature called for aid,
And how'ring Death prepared the blow,
His vigorous remedy display'd
The power of art without the show.

No summons mock'd by cold delay,
No petty gains disclaim'd by pride;
The modest wants of every day
The toil of every day supplied.

Donald Napier was a surgeon who inherited mechanical genius, and though he devoted himself specially to dental surgery, he constructed and improved many ingenious surgical instruments. The Association of Surgeons who practice dental surgery owe a great deal to Napier's zeal, and he did very much, although he died at fifty, to improve the position of dental surgeons.

Although he lived a little beyond the metropolitan district, the noble figure and grand head of Heckstall Smith were almost as well known to us in London as in Kent, where he practiced for more than fifty years. He was a general favorite; did much useful sanitary work; and has left a church, which was built and endowed almost entirely by his exertions, to perpetuate his memory.

Nor should we forget Hardwicke, who left practice on being elected Coroner for Central Middlesex, and died at his post.

Turning from London to the provinces, I again speak first of men who reached old age.

Thomas Radford, who attained the age of eighty-eight, and for sixty-three years had been associated with St. Mary's Hospital for Women in Manchester, enriched that institution by presenting to it a library said to be one of the most complete of its kind in Europe, and by founding a museum. His work on the Cæsarean section is too well known to call for more than mention here.

Stephens, of Shields, was an octogenarian whose services to the town he served were gratefully acknowledged. Greenhow, of Newcastle, was one of the original Fellows of the College. At his death,

at the age of ninety, there was only one senior Fellow on the list. He was a bold, skilful, and successful operator. He had unusual success in lithotomy, and repeatedly excised the os calcis for caries. He had a very large experience in ophthalmic surgery; and invented a very useful fracture bed. During the cholera epidemic in 1832 he labored incessantly, and, twenty years afterwards, foretold the second epidemic, which arrived as he predicted. And he pointed out how, by overcrowding, by burial of the dead within the town, by bad drainage, bad water, and impure air, his townsmen were prepared to fall victims to the pestilence.

Gore, of Bath, also an octogenarian, was of great service to that town in the improvements he obtained in its water-supply and general sanitary administration. Green, Superintendent of the Birmingham Lunatic Asylum, died at eighty-one. Williams, of Swansea, who died at the age of seventy-nine, was the son of a surgeon who practiced nearly a century ago, and was at that time the only member of this College in South Wales. Two surgeons of provincial hospitals—Symonds, of Oxford, and Nunn, of Colchester—were old friends of mine. In many anxious cases they have shared with me serious responsibility, and I am indebted to both for much assistance. Symonds was one of a representative medical family—son of an Oxford surgeon—brother to the eminent physician of Clifton—and father to the present able and active surgeon to the Radcliffe Infirmary. He well maintained the social position of our profession in the university and the county where he was so popular. Nunn thoroughly deserved the place he held for so many years as the most fully employed surgeon in his town and district—a trusted consultant by his brethren, and a warm supporter of the hospital, where he earned the gratitude of the poor.

Drewry Ottley, who died last month, aged eighty, joined this College thirty-six years ago. He was the author of the best Life of John Hunter—that published with Palmer's edition of Hunter's works. After many years' practice in London he settled at Pau, where he remained for more than twenty years, but for several years past has lived in retirement near London. His loss is regretted by many old friends. His son, Walter, one of our Fellows, died only a few days after his father.

John Postgate was a most successful teacher in Birmingham, and did much to prevent adulteration of food, drinks, and drugs. Several bills were introduced into Parliament by the members for Birmingham, influenced by Mr. Postgate, and the amended Acts of 1872 and 1875 are mainly due to his exertions.

Time alone prevents me from alluding to many other of our deceased brethren whose average age at death represents for each about thirty-five years of professional work. Pray consider for a moment what that work is. Walter Scott wrote, "I have heard the celebrated traveller, Mungo Park, who had experienced both courses of life, rather give the preference to travelling as a discoverer in Africa, than to wandering by night and by day the wilds of his native land in the capacity of a country medical practitioner." Only a small proportion of our brethren have acted purely as consultants or operating surgeons. By far the larger number, some without, but more with, some medical qualification in addition to our diploma, have been the general practitioners, or "family doctors" of the people—the trusted medical attendants of at least nine-tenths of the population. Wherever their lot may be cast, in town or country, they instruct both rich and poor how to preserve health, and remove or avoid known causes of disease. And although

little may be recorded of many, we do know that the nation is as much indebted to them as to any other class of public servants. By night and by day, at the service of anyone who may require help in sickness, at the opening or the close of natural life, in mental aberration or in bodily suffering, injured by wound or accident, at almost any distance, in any weather, sometimes suffering themselves from illness or over-fatigue, the members of this College, often without expectation of reward, perhaps bestowing money hard earned and ill spared, as well as affording surgical aid to the needy, ungrudgingly, cheerfully, gladly do their duty day after day and year after year, until, "unknown, unhonored, and unsung," they rest in peace. But no—not *unhonored*. There may be no monumental epitaph, no biography nor memoir, nothing beyond the erasure of a name from the College Calendar, and yet the nation has lost a good and faithful servant, whose place must be filled by others, who in their turn pass through our portals and enter upon the work which is prepared for them.

And it is the most important duty of this College, while maintaining the scientific value and character of its diplomas, to guarantee to the public useful and skilful practitioners, really fitted for the daily practice of the healing art. In order to ensure the value of the diploma as a proof of education and knowledge and skill, the Council and the examiners, recognizing the necessity that the surgeons of the future must be well-educated gentlemen, and that their scientific and practical knowledge shall fit them for their daily work, have been earnestly endeavoring to fill up our ranks by attracting, as far as possible, young men who, before they begin professional studies, have had the advantage of as high general culture as can be obtained in our best schools. In this desire we have the hearty concurrence of the Medical Council and of the College of Physicians; and I trust the day is not far distant when, without either aid or interference from the State, the two Royal Colleges will correct mistakes in the working of the Medical Act, prescribe a common course of study for students, and agree upon a mode of examination which shall secure for the country a body of well-educated medical men, who, either as teachers or as students in the metropolis or the provinces—as army or navy surgeons or as civilians; at home or abroad—by observation, by research, by experiment, by improvements in the practice of our art, by additions to our literature, by daily attempts to relieve the sufferings of others, may emulate the best of their predecessors, and, like them, while living be honored and loved, and when dead, not forgotten.

So far I have spoken of deaths among our brethren at home. In India, in our Colonies, at sea in our Navy, or in our mercantile marine, other losses might be deplored. But I must pass on to speak of some of the army surgeons, who in India, at the Cape, and in Egypt, have done honor to their country and their calling. Brigade-Surgeon Martin, who died in India last March, was mentioned in despatches as "attending to the wounded under heavy fire."

Forty years ago, one of our oldest Fellows, whom we all congratulate upon continued vigorous health and continued interest in the progress of modern surgery—a teacher of many who are now themselves teachers—Mr. Arnott—when delivering the Hunterian Oration, spoke of the great French army surgeon, Larrey, who had recently died, as "the first military surgeon who dressed the wounded under the very fire of the batteries," and said that to him we "owe our place of honor on the field of battle." The army surgeons of our

day well maintain their reputation, not only for gallantry, but for self-sacrifice to duty. What can be finer than the conduct of Shepherd, who, riding away from the bloody field of Isandhlwana, with a good chance of escape, dismounted to assist a wounded man, and was killed by the assegais of the Zulus; or of McCrea, who, severely wounded in the chest himself in the first charge, continued to attend the other wounded, as he was the only doctor on the field.

In the military operations on the Transvaal frontier against the Boers, the courageous devotion of army-surgeons to their duty was conspicuous. At Lang's Neck, "As the 58th Regiment advanced, and the men were falling rapidly, Surgeons King and McGann moved up behind the advancing column, and, on its retirement, remained, amidst a hail of bullets, attending to the wounded. At the final disaster of Majuba Hill, the officers of the medical service remained faithful to their duties even unto death. Dr. Cornish was shot as, with a piper of the 92nd Highlanders, he was carrying a wounded man on a stretcher. Landon, always keen for duty in the field, and taking a special pride in his Army Hospital Corps, met his fate at the final rush of the Boers. The ruling passion strong in death, he called Dr. Babington's attention, shortly before he expired, to the meritorious conduct of his men." I have copied this from a colonial newspaper, the *Natal Witness*. Let me say something more about Landon. He was kneeling, attending to a wounded soldier, when a bullet wounded him in the loin, and Longmore writes: "He at once fell forward. The lower half of his body became completely paralyzed, and Landon told Corporal Farmer he must die. Farmer was almost immediately struck by a bullet in both his forearms, and was suffering excessive pain from injuries to the ulnar nerves. Landon had a field case with him containing morphia and syringes, and he had the upper part of his body propped up against a boulder of rock, and in that position administered the morphia injection in both Farmer's arms in succession. The corporal was so relieved that he fell asleep, and remained so for several hours." Well may Longmore write: "It is difficult to imagine a more perfect example of professional heroism than was afforded by the conduct of Surgeon Landon, from the time when the Majnba fight commenced to that when death put an end to his own sufferings." And well have the men of St. Bartholomew's done by placing a tablet in their chapel, to keep in memory his bright example, by a record of his last words—"I am dying; do what you can for the wounded." And not Bartholomew's men only—not only this College—not army surgeons only, but the whole profession, the whole nation, will rejoice with me when it is made known that her Majesty the Queen was so much impressed by the story which I have just read to you of Landon's noble conduct, that the report has been preserved among her private records—another proof of the Queen's interest in her soldiers, and in the men who are devoted to them.

The last Egyptian campaign has added another to the list of Army Surgeons killed in action while attending to the wounded. George Shaw had served in cholera camps in India, in the field at Afghanistan, and in the advance through the Khyber. He was a very gentle, amiable man, most devoted to the soldiers. He went to Egypt with the Bearer Company, and at Kassassin, while dressing the wounded under fire, was shot through the head.

It is gratifying also to be assured that in Egypt, as in South Africa, the men of the Army Hospital Corps worked as bravely and as well as the ex-

amples of the medical officers led them to do. My old comrades, the Naval Surgeons, also deserve full credit for the way they did their work during the Egyptian campaign—on board ship at the attack on the forts of Alexandria, or on shore with blue jackets and marines, alike under fire with the fighting line, or in the armored train, or combating disease in camp, or on the march. We have been assured by everyone in a position to know—from the Commander-in-Chief downwards—that the naval surgeons were always ready, willing, and cheerful. And while we speak with pride and satisfaction of the manner in which our brethren, both in army and navy, who served at the seat of war acquitted themselves, we must not forget those who labored at home: the heads of both the medical departments and those under them have well-merited a generous recognition of their forethought and good service.

And what a change for the better has taken place in the practice of army surgeons since Hunter's time! Military surgery, before the publication in 1794 of his last work, so far as the treatment of gunshot wounds is concerned, was influenced by the false doctrine of the poisonous nature of the wound—the necessity for the escape of the poison—and therefore for the dilatation of the wound and the keeping up of suppurative discharge. Hunter served as Staff Surgeon in the army in the expedition against Belleisle in 1760, and in Portugal in 1763. In 1776 he was appointed Surgeon Extraordinary in the Army, in 1786 Deputy Surgeon-General, and in 1791 Surgeon-General—as Longmore says, "a laborious office, corresponding with that of the Director-General under existing arrangements." He held this office during the early part of the war with France which preceded the peace of Amiens. After Hunter's death the simpler treatment of gunshot wounds which he taught has been generally followed, and other great improvements in military surgery have been accomplished. Secondary amputations have been shown to be more fatal than those performed soon after the wound. Amputations have been often avoided by excision of joints or of injured portions of bone. The use of anæsthetics, and latterly of antiseptics, in spite of the much larger number of wounded after modern battles, have greatly lowered the death-rate; while, thanks to our experience in the Crimea, and the perfection of the system of ambulance transport in our Indian army (all admirably worked out by the indefatigable perseverance of one of our Fellows, the Professor of Military Surgery at Netley), the transport of our sick and wounded in time of war is so perfect as to have been copied by other armies; while all the administrative arrangements for the care and treatment of sick and wounded, the organization of military hospitals in time both of peace and of war, and the service in the field, were proved in the late Egyptian expedition, under all the disadvantages of a rapid and unexpected change of base, to have been most creditable to the Army Medical Department. If this department obtains such a control over its own affairs as other branches of the army, we need not fear for its future efficiency. To ensure this efficiency the medical officers and the Army Hospital Corps should be made one Royal Corps, placed on a perfect equality with other corps, and receive a fair share of honorary distinctions. The Director-General and the principal medical officer of a division should be secured rank and pay proportionate to their arduous and responsible duties, and be provided with a subordinate for secretary's duty. A field hospital fully equipped for the field should be maintained at Aldershot or elsewhere, and the whole corps be frequently exercised dur-

ing peace in all the duties they may be called upon to perform in war. Let us trust that this may be the result of the Commission which has been sitting under the presidency of Lord Morley, and of which one of our Fellows, Sir William Mac Cormac, is a member. Under their own head, a united body, having entire control over and command of their own Department, subject only to the general officers commanding, our army surgeons will cheerfully accept the responsibility of collecting, removing from the field of battle, and attending to the first wants of the wounded, and for their subsequent care and treatment, as well as for the equally important duties of sanitary officers in preventing disease and maintaining the physical condition of our army. And if the corps desire a motto, let me suggest one, well-deserved by their conduct in the past, and encouraging to good service in the future—"FAITHFUL UNTO DEATH."

I must now obey the other direction in the trust deed, and endeavor to express something as to the "merits in comparative anatomy, physiology, and surgery" of John Hunter. The direction seems a happy one, for Hunter based his surgery upon physiology, and his physiology upon comparative anatomy. What can more strikingly illustrate this than his greatest improvement in practical surgery, the abolition of amputation for popliteal aneurism, and the practice of tying the artery in a sound part at a distance from the seat of disease? This has already saved thousands of human lives; and it has been well said that if Hunter had done nothing else, "on this account alone he would have a right to be classed among the principal benefactors of mankind."

One who perhaps more than any other of our contemporaries resembles Hunter in completing the union of thought with action—the wisdom of the philosopher with the skill of the surgeon—Sir James Paget—says, "It was really a splendid achievement, and its utility is not half told by counting the thousands of lives that it has saved. Its higher value is that it still abides as a great testimony of the power of the scientific mind in surgery. I think it has done more than any other of Hunter's works to make, not only surgeons, but surgery, scientific." And observe how comparative anatomy and physiology led to surgery—how thought and experiment prepared the way for action. It was probably without any idea of surgery that Hunter was first led to investigate the phenomena of the annual growth and shedding of the antlers of the stag or buck. But he did so, and tied the artery which supplies the growing antler and the soft covering called the "velvet," which conveys the vessels supplying the material of growth. Pulsation in the vessels in the velvet ceased, and the antler soon became colder. A week afterwards the vessels were again pulsating, the velvet was warm, and the antler growing. The buck was killed, the tied artery found to be obliterated, but the circulation was carried on by vessels above and below the ligature, ordinarily very small, but enlarged under the new conditions.

Now I am well aware that some modern misanthropical zoophilists have said that Hunter had no right to make this experiment—that human morbid anatomy had taught him that when the current of blood ceased to flow into an aneurismal sac, the blood clotted and was absorbed. But it is quite indisputable that Hunter was doubtful whether, after the supply of blood to a part had been cut off by obliterating the main arterial trunk, the circulation would be kept up by other vessels, or the part would die. And it is certain that his experiment on the deer removed his doubts, for, as Professor Owen tells us, there was a coachman

in St. George's Hospital, with popliteal aneurism, who had consented to amputation. But Hunter thought that if the anastomizing vessels in the man would carry on the circulation after obliteration of the femoral artery, as they did in the antler of the buck after obliteration of the carotid, he could cure the aneurism and save the limb. Professor Owen emphatically says that Hunter explained to his assistant and pupils the results which he believed would follow a repetition on the man of his experiment on the deer. And, just as he predicted, there was the same stopping of pulsation, the same cooling of the part from which the supply of blood was cut off, the same return of natural warmth, and in six weeks the man walked away cured. This account, Professor Owen tells me, was given to him by Mr. Clift. In this and two subsequent cases artery and vein were both tied; but in his fourth case Hunter tied the artery only, not the vein. This was in the year 1787. The patient was then thirty-seven years old. He lived until he was eighty-six, and died in 1787. At his death, Mr. Wormald obtained the limb from his widow, and found the femoral vein pervious, the artery obliterated, the tortuous anastomosing vessels as you see them in this specimen which Mr. Wormald presented to our museum, and the aneurism represented by the small calcareous body not larger than a filbert.

This association of surgery, physiology, and comparative anatomy is manifest in the leading idea or plan of Hunter's museum, which is to show each step from the most simple conditions in which life can be traced upwards to man himself. We are told, observing that in the advanced stages of successful incubation eggs did not putrefy, he was first led "to recognise LIFE as a power, and ORGANIZATION as the mechanism by which life operates." Observing some snails drowning, and noticing the effects produced upon lizards if they were brought too early in winter out of their lurking-places, he ascertained some of the facts "which guide and encourage us in our attempts to restore suspended animation." Here we see the man who both observes and thinks. "For one person who can think," says Buckle, "there are at least a hundred who can observe: an accurate observer is no doubt rare, but an accurate thinker is far rarer." Can anyone look up to this portrait of Hunter, by Reynolds, and not agree with Lavater, who, when he saw it, said, "This man thinks for himself?" Hunter used to say that "he delighted in thinking;" and the great artist who is said to have peculiarly excelled in *painting the mind* of his sitters, has caught Hunter in the attitude of meditation. In that absorbed and upward gaze "from earth to heaven," "as imagination bodies forth the forms of things unknown," we can trace the hoped-for explanation of some of the mysterious phenomena of nature by the application of some great leading principle, the elucidation of some physiological problem, the unravelling of some as yet unfolded revelation. Home and others who knew Hunter have said that this portrait gives a very faithful representation of his countenance, person, and manner. While painting the portrait, Reynolds induced Hunter to have a cast taken from his face. From this cast, which has been preserved in our museum, and is here before you, Flaxman's marble was sculptured. He and Chantrey studied both cast and portrait, for the College is fortunate in possessing two busts of our great master, as well as the full-length sitting figure in the museum by Weekes. And we have a second portrait, by Sir Nathaniel Holland, which was said by Mr. Clift, and by Sir John Dorat, Hunter's last surviving pupil, to be better as a mere likeness than the idealized portrait by Reynolds. Per-

haps Reynolds's portrait is more suggestive of the man who thought, and Flaxman's bust of the man who observed, experimented, acted.

Though Hunter loved to think, he followed Bacon in insisting on observation and experiment as the only foundations of true science. "If you check experiment you stop discovery" is one of his aphorisms. And he once wrote to a friend, "I think your solution is just. But why think? Why not try the experiment? Repeat all the experiments as soon as you receive this, and they will give you the solution." Thus in Hunter we find the mind which investigates the laws of disease, and the hand which improves the art which cures disease, not only philosopher and pathologist, but surgeon—as rare a combination as that of a profound jurist and an eloquent advocate—an agricultural chemist and a farmer—an astronomer and a pilot. We have a combination of Faraday investigating the laws of electricity and magnetism, and Swan or Edison applying the knowledge in the electric lighting of towns.

It is unnecessary to repeat now, what Mr. Wormald proved in this place twenty-five years ago, that Hunter was well aware of the possibility of curing aneurism by pressure on the artery as well as by tying it—in this, as in so many other instances, anticipating recent improvements in practice supposed to be new. Just as we find that modern views of phlebitis and pyæmia had been advanced by Hunter; and Burdon Sanderson, in his lectures on inflammation, acknowledging that "we find ourselves once more coming back to the notions, which at one time were thought obsolete, of the great father and founder of physiological pathology;" so we may be certain that Hunter foresaw much of that progress in abdominal surgery in which it has been my own pride and pleasure to assist. In 1762 William Hunter distinctly suggested that it might be advisable to expose an ovarian cyst by a small incision—"tap the bag and draw it out." In 1785 John Hunter said "I cannot see any reason why . . . we should not make an opening into the abdomen and extract the cyst itself. Why should not a woman suffer pain without danger as well as other animals do?" The influence of Hunter's teaching upon John Bell, of Bell upon McDowell, and the history of ovariotomy since McDowell's first operation, is a theme which I have treated at length in this theater and elsewhere; and however strongly tempted to enlarge upon it, and upon the more recent extensions of peritoneal surgery—the removal of uterine tumours, of the spleen, of one kidney, of hydatids, of gall-stones, of omental and mesenteric tumours, of fibro-plastic and fatty tumours of various origin from the abdomen, of the entire uterus, or of part of the uterus with the foetus of an extra-uterine foetation, of the pylorus, and of portions of diseased intestine—all operations which have been performed with increasing success—I regret very much that I have not time to do more than point to the preparations on the table, which show how our younger hospital surgeons are joining in the most recent advances of abdominal surgery. Mr. Treves's specimens show how perfectly union between two portions of intestine may be effected after the removal of an intervening diseased portion. And the three large gall-stones removed from the gall-bladder of a woman in the Samaritan Hospital by Mr. Meredith are gratifying evidences of boldness and skill. Both Mr. Treves and Mr. Meredith, at my suggestion, were desirous of experimenting on some of the lower animals as to the best mode of uniting divided edges or surfaces of peritoneum; but the trouble and delay of the present system of licensing has hitherto restricted their operations to man and woman. I

wish I could say more of this, but I am compelled to devote the very few minutes allotted to me to a hasty sketch of what we hope may be gained in the not very distant future by combined association for the advancement of medicine, in its higher sense, by research.

And first let me say with how much pleasure I can state that the Association lately founded under the auspices of all the leading men in our profession in the United Kingdom has already begun useful work. On the part of the Association, Mr. Watson Cheyne visited Dr. Koch at Berlin, and Professor Toussaint, at Toulouse, and has since carried on investigations, the results of which enable him to explain their opposite statements with regard to the micro-organisms associated with tubercle. Mr. Cheyne has also made experiments with reference to the specific nature of tubercle, which tend to confirm the view of the specific nature of tubercle first promulgated by Villemain, and so strongly supported by Koch's observations. Mr. Cheyne's further observations lead him to the conclusion that the bacilli of tubercle multiply by preference in the epithelium of the aveoli of the lungs, and lead to inflammatory exudation in the walls of the aveoli. According to the number and rapidity of growth of the bacilli in the aveoli, we have the two conditions of fibroid phthisis or caseous pneumonia, which by many have been looked on as different processes. On this view is also explained the difference in the effects produced by these organisms in man and rodents. Rodents, when inoculated subcutaneously, always develop general acute tuberculosis. That disease is extremely rare in man when compared with the frequency of pulmonary tuberculosis; because in man the bacilli are not inoculated, but are received into the bronchial tubes by inhalation, and their entrance into the circulation is prevented in the first instance by the inflammatory changes which occur around the aveoli in which the bacilli grow. If man were inoculated as we inoculate rodents, all analogy would lead to the conclusion that acute tuberculosis would probably be developed. Mr. Cheyne is carrying on these researches, the animals experimented on being kept under exceptionally favorable hygienic conditions, and it is not too much to hope that they may lead to a successful mode of treating phthisis. However strongly tempted to say more on this immensely important subject, I must leave it for a future Hunterian orator, and pass from tubercle and its bacilli to other diseases, more commonly classed as contagious or infective.

Of all the discoveries of modern times, perhaps the most important is that of the dependence of fermentation and putrefaction upon microscopic organisms; and of a number of communicable diseases upon specific microbes—a convenient word to include the micrococcus, the bacterium, the bacillus, the vibrio—microzoa or microphytes, whichever they may be.

At Cambridge, eighteen years ago, I attempted to show the relation between the work of Davaine and Pasteur, and the causes of excessive mortality after surgical operations. Allow me to read one sentence from my address in 1864, partly to allude to advances gained since that year, and partly to point out some lines of future research. I said: "Applying the knowledge for which we are indebted to Pasteur of the presence in the atmosphere of organic germs, which will grow, develop, and multiply, under favorable conditions, it is easy to understand that some germs find their most appropriate nutriment in the secretions from wounds, or in pus, and that they so modify it as to convert it into a poison when absorbed—or that the germs after development, multiplica-

tion, and death, may form a putrid infecting matter—or that they may enter the blood and develop themselves, effecting in the process deadly changes in the circulating fluid."

In the history of this discovery we find Davaine discovering bacteria in the blood of animals suffering from charbon. Then, having studied Pasteur's researches on butyric fermentation, Davaine found that he could propagate a fatal disease, not only by a purulent virus, but by a drop of infected blood. It was left for Pasteur to separate and identify the microbe, to propagate it through successive generations, and to arrive at a general rule that a whole series of contagious diseases could be produced artificially, and that the microbe which was the cause of each disease could be so modified by successive cultivation, some with, some without, access of oxygen, as to be rendered almost inert—nay, more, even to protect the recipient for a time from a second invasion, and secure immunity to the offspring of infected mothers.

I must not go back to the history of vaccination as a protective against small-pox, nor remind you that Jenner was a pupil of John Hunter, nor refer to many of the letters which passed between them; but I may notice a resolution of the Council of this College carried sixty years ago—"not to inoculate small-pox, but to pursue, and to the utmost of our power promote, the practice of vaccination." We persevere in this course. We require every candidate for our diploma to produce proof of practical knowledge of vaccination. We support the law which protects the many from the danger to which a few ignorant opponents of compulsory vaccination would expose the whole population. And as we glory in the life-saving work of our countryman, Jenner, so we welcome the teaching of the illustrious Frenchman, Pasteur, and his extension of the protective influence of vaccination to other diseases—every year adding to the list of new vaccines which protect man and animals against virulent diseases.

When I first thought of the subjects for this oration, I had a very exaggerated idea of what it might be possible to do in sixty minutes. I hoped that (in addition to what I must say of our deceased brethren, and of John Hunter himself), of recent additions to our museum, and of the new Pathological Catalogue, I might be able to indulge in a review of the progress of modern surgery, and perhaps compare the present state of medical practice in London with that in Hunter's time, or even to take a hasty review of the progress of the nation since his death, and refer to the rapid increase of population and wealth, the discovery of steam, the influence of railroads and steamships, the use of gas, of the electric telegraph, the spread of education, the effects of newspapers and cheap literature, of reforms in our laws, improvements in our habits, and many other things which tend to make a people wiser, happier, and better. I even thought it might be possible to sketch very rapidly the share which the medical art, in its larger and wider sense—not only as curing but as preventing disease—has had in assisting national progress, and to prove that neither medicine nor surgery has lagged behind the general advance. I hoped I might be able to prove beyond dispute that since active sanitary work has been undertaken in this country death rates have fallen very greatly, and fallen most in those places—the great towns—where sanitation has been most active. I was very anxious to show how the knowledge gained by the statistical work begun by Dr. Farr, and since carried on by Dr. Ogle at the General Register Office, had led to sanitary legislation, and how sanitary work has been fol-

lowed by a lower general death-rate and smaller mortality in single forms of disease, as in typhoid fever, as well as after wounds, injuries, and surgical operations. I wished also to show how statistics lead to the saving of life by throwing light on the natural history of disease, on the prevalence of various zymotic diseases at different seasons, and on the indisputable proofs that small-pox has declined considerably with the extended use of vaccination, that it is false to attribute that decline to general sanitation, exclusive of vaccination, and, what is a more novel or less generally known fact, that we have statistical proof that the preservative effects of vaccination wear out more rapidly and surely than the preservative effects of small-pox itself. I imagined also that I might be able to sketch what the nation might gain if State Medicine were really administered by a well-organized department of the Government, if politicians of both parties could be roused from their indifference to social or domestic legislation and give some small share of their attention to the health-interests of the people—to their food, drink, occupations, house accommodation, care of infants, prevention of infective diseases, local sanitary administration, and many details of sanitary reform, such as a permission or encouragement of cremation as a substitute for the present mode of burying the dead.

My intentions, sir, may have been good, but their fulfilment is impossible; and, in conclusion, I can only refer to the prospect which expands before us as we are shown that more than thirty destructive diseases, including tubercle and typhoid fever, ague and yellow fever, scarlatina, diphtheria, erysipelas, syphilis, and septicæmia, in man; in the lower animals, splenic fever, fowl-cholera, cattle-plague, glanders, hydrophobia—all depend upon specific microbes. In many of these thirty diseases, the specific microbe has been identified beyond dispute. In some, the process of attenuative culture has transformed a poisonous virus into a protective vaccine. In others, we may confidently hope that the same happy result will soon be reached; and as we have already acquired the knowledge of certain specifics, it is not illogical to infer that if we can in one instance command the good results we see with mercury, in another with sulphur, and in a third with quinine, we may before long obtain such a knowledge of the various microbes which are the cause of communicable diseases, as may teach us how to destroy these organisms, or to arrest or mitigate their morbid influence, and so check, if not stamp out, some of the diseases which are now our most formidable difficulties. We may then congratulate mankind that the science of our own time has conferred not only upon man, but on the whole animal kingdom, benefits equalling any which it owes to the lucky empiricism of past ages, or to the philosophic genius and marvellous industry of John Hunter. And we his followers may be encouraged by the conviction that we so cultivate our science and our art (devoted as they are to the public good) as to justify us in keeping our old motto, "*QUE PRO-SUNT OMNIBUS ARTES*."

—We regret to announce the death, after a short illness, of Dr. Shinkwin, of Cork, at his residence, North-mall, Cork. Deceased was a graduate in Medicine of the University of Aberdeen and of the Queen's University in Ireland, and held the post of Senior Surgeon to the North Charitable Infirmary. Dr. Shinkwin was the author of a work on Hydrophobia, and leaves a widow and two children, besides a large circle of friends, to mourn his loss.

Clinical Lecture

ON A

CASE OF CEREBRAL DISEASE,

PROBABLY A

GROSS LESION OF THE BRAIN.

LOSS OF SIGHT, HEARING, SMELL, TASTE, AND FEELING;
DOUBLE OPTIC NEURITIS; UNILATERAL CONVULSIONS;
HEMIPLEGIA, ETC.; ENDING IN COMPLETE RECOVERY.

By A. HUGHES BENNETT, M.D.

Physician to the Hospital for Epilepsy and Paralysis, Regent's Park, and Assistant-Physician to the Westminster Hospital.

THIS case is of great interest on account of the grave and important symptoms which were developed, and from the fact that these ended in complete recovery. The following account is abstracted from voluminous notes:—

A. D., age one year; male.

Antecedent history.—The parents of the patients state that they are both in perfect health, never having suffered from any illness. The father, who is a very intelligent man, says that there is no history of syphilis in the family. All the other children are in robust health; but two of them are said to have had "fits" when teething, but have since been quite well. The patient himself was in good condition till he was six months of age, when, without obvious cause, he had his first "fit." These attacks have continued since, and he has had 170 up to the present date. At first they were only occasional, but of late he has been having a dozen or more during the twenty-four hours. They occur for the most part during sleep, but also occasionally while the child is awake. The convulsions are almost always confined to the left side, but the mother says that sometimes all the limbs are affected.

Present condition.—June 23rd, 1879: The child is well nourished, its general health is good, and its functions appear normally performed. It lies with a dull, vacant look, and although it is stated to have been formerly very intelligent and even-tempered, it is now fretful, cries, and "takes no notice of anything." The right side of the forehead is markedly more prominent than the left, and projects forward in a rounded swelling, about two inches and a half in diameter. The bones forming the anterior fontanelle are at their edges raised and thickened. The child is unable to hold up its head, which falls about in all directions unless supported. There is external strabismus of both eyes. It is difficult to ascertain the exact movements of the eyeballs owing to the youth and condition of the patient. The pupils are equal and normal. The face is straight. All four limbs are of normal appearance; but it is impossible to ascertain their precise condition, although it is evident that they are weak, especially on the left side. The patient is stated to have ten or twelve attacks every day. One of these I saw during a visit. Suddenly, after a cry, the face began to twitch, and was drawn towards the left side; then the head was inclined to the left, and both eyeballs turned in the same direction. The left arm and leg were convulsed and contracted, and became rigid; but it was difficult to say which of them was first affected. The entire right side remained immovable. The child during the paroxysm, which appeared to last about ten seconds, was apparently insensible. After the attack he was drowsy, and slept for nearly an hour, when he regained his ordinary condition. This,

the mother says, was "an ordinary fit," but sometimes it is more severe, lasting longer, with biting of tongue, and accompanied with more violent and general convulsions.

Progress of the case.—June 30th.—During the past week the patient has had about one hundred attacks, but otherwise he remains much the same as before.

July 7th.—The attacks continue with equal frequency. To-day on examination the patient is found in a semi-comatose condition; he lies in his mother's arms, limp and helpless, the head and limbs dangling about unless supported. The mother says he is always in this partially unconscious condition. The mental state, owing to the youth of the child, is difficult to analyze, but is peculiar. The consciousness is not completely lost, as the child is restless and fretful when irritated; it knows when food is given to it, but yet evinces very few signs of real intelligence. All the reflex and automatic movements seem as in health; nourishment is taken well, and the functions are normally performed. The eyelids are closed, the conjunctivæ are not sensitive to touch, and the eyeballs diverge, both looking outwards. The left arm and leg are completely paralyzed, but the other limbs move apparently by volition. The mother says the child is both blind and deaf, and indeed, the functions of all the senses seem abolished, as far as can be determined by experiment.

21st.—During the past fortnight there have been no attacks. The general condition has fluctuated, the patient sometimes remaining comatose for several days, at others recovering to a certain extent. At the visit the child was in one of his more lucid intervals. He lay still, with the eyelids widely open, the pupils both dilated; he was still apparently sightless and deaf; the conjunctivæ were insensitive to touch; the mouth remained open, and the saliva constantly trickled down the neck; the tongue lolled out with a continuous vibratile movement. The face was drawn slightly to the right side. The left arm and leg were rigid, and the joints were partially contracted, but there were occasionally feeble voluntary movements. There was sometimes tonic spasm of the muscles of the neck, so that the head was drawn backwards and to the left. There had been occasional vomiting, and the child suffered from a constant tickling cough. On examination of the eyes, Mr. Laidlaw Purves reports, well-marked double optic neuritis, both discs being swollen and grey, with their edges ill defined.

For the next two months the patient remained in much the same condition as has just been described, so ill that he was daily expected die. He was constantly semi-soporose, cried and screamed almost without ceasing, and was very fretful and restless. The paralysis of the left side continued, but was frequently varied with twitchings and spasms. During this time no actual fits were observed. The swelling on the right side of the forehead was very prominent, as was also the thickening of the frontal and parietal bones. The eyeballs were almost always deviated towards the left side during the attacks, but when at rest there was generally external strabismus in both. The child slept very little, but continued to take its food well. It had become very much emaciated.

Oct. 6th.—The report to-day states that till about a week ago the patient remained in the above condition. About this time the mental state changed, and sight, hearing, and taste somewhat suddenly returned. The child looked about, followed movements with its eyes, etc., it started when a door was slammed, and showed by its actions that it disliked castor oil. To-day it

laughed and evidently "took notice." It now moved the left side; and when the right hand was held it grasped a penny, but awkwardly, with the other. The child weighed thirteen pounds.

13th.—The improvement continues. The face and eyes are normal. The intelligence appears natural, the child laughs, plays with its toys, and takes an interest in all going on around it. Although still much emaciated, it takes food well. It has no convulsions or attacks of any kind. There is now no rigidity or contracture of the limbs, and, although the movements on the left side have improved, they are still considerably impaired. The swelling of the frontal region appears smaller, and the thickening of the parietal bones has almost disappeared.

For several weeks the advance progressed favorably; and although the child had bronchitis and diarrhoea, it had gained nearly a pound a week in weight.

Dec. 1st.—To-day the report was: The patient is now plump, red-cheeked, and healthy looking, and weighs nineteen pounds and a quarter. It is lively, good-natured, and intelligent, sits up, and plays about like other children. The appetite, the mother says, is alarmingly voracious. There is still enlargement of the right frontal region, but the thickening of the other bones has completely subsided. The movements of the face and eyes are perfectly normal. Sight, hearing, and the other senses are intact. The actions of the limbs are vigorous, but it is evident that the power of the left arm is still somewhat impaired, and its more delicate manipulations are awkward. Both legs are apparently equal and normal.

March 23rd, 1880.—Patient has remained well and is now in perfect health. There is no trace of paralysis of any kind.

Nov. 14th, 1882.—To-day—that is, three years and a half since the patient first came under notice—I saw him. He has grown a robust, handsome boy, is perfectly intelligent and active in all his limbs. There is no trace of anything abnormal about him, except that the right frontal region is slightly fuller than the left. All the senses are normal, and Mr. Purves reports the optic discs to be perfectly healthy.

Commentary.—If this case is of little pathological value, the patient being still alive and now free from disease, it is of considerable clinical interest. It may be taken for granted that the brain was the organ affected. The next point to determine is whether the disease was of a so-called functional or of organic nature. I am of opinion that there was a gross lesion of the encephalon. This seems to be evidenced by the train of general symptoms, their grave and permanent character, the local convulsions and paralysis, the unaccountable vomiting, and by the signs of intra-cranial pressure, as indicated by abeyance of the intellectual faculties and of the special senses, and the appearance of the circulation and optic discs in the fundus of the eyes. This intra-cephalic pressure caused definite cerebral phenomena. The perceptive faculties were suspended; the child for months lay in a semi-comatose condition, the functions of the body being carried on, and the movements of the muscles being performed, in apparently an automatic manner. Food was taken and digested; the bladder and rectum were evacuated; the patient was cross when irritated; and the reflex acts were normal; but for long he showed no signs of voluntary acts or of intellectual efforts. The sight, hearing, smell, taste, and feeling seemed to be completely abolished. There was no evidence, however, that the organs of these senses were themselves directly involved in the disease, as

they subsequently completely recovered. The probability rather is that the child, owing to the intra-cranial pressure, had lost the power of receiving mental impressions of any kind, and was incapable of appreciating or responding to them. Again, in addition to the local spasms and paralysis, there was general loss of power throughout the body, and occasionally during the epileptiform attacks all the limbs were convulsed. Finally, the condition of the fundus of the eye gave ocular demonstration of this general intra-cranial pressure, as evidenced by the characteristic changes in the vessels and optic discs. These facts tend to show that what we suppose to be the gross lesion of the encephalon was of sufficient bulk to cause the symptoms and signs just enumerated.

In addition to these general conditions, there were certain special phenomena which enable us to localize the disease. There were well-marked hemiplegia and convulsions limited to the left side of the body, which permit us to place the morbid lesion on the right side of the brain. An extended consideration of this unilateral paresis and spasm, allows us further to localize the disease to the posterior frontal or parietal regions of the right cerebral lobes. Physiological experiment has demonstrated that these localities on one side are the centres for originating movements on the other, that their irritation causes convulsion and their destruction paralysis. These investigations have been further supported by pathological and clinical observations, and more especially by those of Dr. Hughlings Jackson. In this case there were attacks of universal hemipasm—namely, convulsion of the left side of the face, arm, and leg, the head and eyes being drawn in the same direction. During the intervals of these paroxysms there was paralysis of the left face, arm, and leg, with double external strabismus. These facts indicate implication of all the motor centres on the right side of the brain.

Further analysis of the symptoms enable us even more accurately to limit the existing lesion to the cortical matter of the convolutions. The attacks of convulsions point to instability of grey substance, as irritation in its motor regions gives rise to explosive discharges of movement, hence we may assume that those centres were in an excitable condition. The paralysis on the other hand, which affected the same parts as the convulsions, although permanent during the illness, subsequently completely disappeared. This is an indication that the lesion, capable of producing irritation and temporary abeyance of motor function, had not caused complete destruction of tissue. Assuming a gross lesion to be the cause of both these symptoms, it cannot be admitted that this was situated in the substance of the brain itself; as disease there of sufficient bulk to account for all the phenomena observed would have caused permanent alteration of structure, whereas we know that the patient afterwards entirely recovered without having a trace of functional deficiency. The inference therefore to be drawn from this fact is that the morbid process did not occupy the cerebral lobes themselves, but was situated outside them. The train of symptoms, I think, are best explained on the supposition that the disease was a growth probably attached to the bone or membranes over the post-frontal and parietal regions of the right cerebral hemisphere. This, by general intracranial pressure, caused the intellectual and sensory deficiencies, the universal debility, and the changes in the fundus of the eye. By special influence on the cortical motor centres it induced irritability of the grey substance without actual destruction, hence the paroxysms of convulsions in the parts deriving from them their motor

activity. The same local pressure was also sufficient to cause permanent paresis of the same, which disappeared when the foreign body was subsequently absorbed, leaving the structures, of which it for a time suspended the functional activity, unimpaired.

The nature of the morbid growth must, from absence of pathological data, remain in doubt. Careful inquiry failed to elicit any trace of syphilis in the family history, but the appearances, progress, and termination of the case seem to point to that disease as constituting the local lesion of the brain. On the right forehead of the child there was a marked prominence of the bone, and the edges of the anterior fontanelle were raised and thickened in a manner highly suggestive of syphilitic infection. The termination and result of treatment might also by many be considered corroborative of this view. The patient throughout was treated chiefly with the bromide and iodide of potassium, and recovered under their influence, but whether as a result of the drugs or not I shall not attempt to determine. It is the habit of some authors to found a diagnosis upon the result of treatment, maintaining, for example, that in doubtful cases if a certain disease improve upon an anti-syphilitic remedy, that this in itself is evidence of the correctness of the suspected diagnosis. Such reasoning appears to me to be unscientific, and likely to lead to error, as it assumes as a fact what is by no means universally admitted.

Dr. Hughlings Jackson considers that the presence of double optic neuritis accompanied with unilateral convulsions is strong evidence in favor of specific disease. Doubtless it may be the fact that these are frequently associated, as syphilitic tumours are the most common cause of such local cerebral disorders; but from such symptoms we cannot diagnose syphilis to be present, but can only assert that gross lesion of some kind in the encephalon, involving the grey matter, is probable.

The general conclusions which seem permissible in this case are as follows: 1. That all the symptoms were due to cerebral disease. 2. That the lesion of the brain was gross, and not merely functional in character, and probably consisted of a morbid growth attached to the membranes or bones of the calvaria. 3. That this was of sufficient bulk to cause symptoms of general intracranial pressure. 4. That the lesion was localized, and probably limited to the cortical portion of the right post-frontal and parietal regions. 5. That the symptoms were induced by pressure on, but not destruction of, the nervous elements. 6. That recovery was due to absorption of the morbid product, and subsequent restoration of function of the cerebral convolutions. 7. That the disease was probably syphilitic in character.

Clinical Lecture

ON

PNEUMONIA WITH PERICARDITIS.

Delivered at the Westminster Hospital.

By OCTAVIUS STURGES, M.D.,
Physician to the Hospital.

GENTLEMEN—True pneumonia, commonly, if not invariably, associated with pleurisy, is not very rarely associated with pericarditis also. This latter combination, although receiving less attention than it deserves, is a form of the disease which is interesting on many accounts, and especially as regards its treatment. For this reason I take ad-

vantage of an example of the kind lately in Burdett ward to make a few observations upon the subject this afternoon. The case, very briefly abstracted from notes of Mr. Hebbert, the medical registrar, is as follows:—

William M—, aged thirty-two, a porter, of free drinking habits, but not a drunkard, and of whom it was stated with much distinctness that "he had never been laid up in his life," was brought to hospital on Dec. 27th, with the signs of acute pneumonia of the left lung. The initial rigor had occurred five days before, after a definite exposure, but for some weeks he had not been in his usual health, complaining of cough, weakness, night sweating, and some wasting, yet without having to keep his bed till the commencement of the acute attack. Cough, rusty sputa, great thirst, and an unusual degree of prostration had been noticed during the early days of the pneumonia, and for two nights before admission he had been sleepless and delirious. The circumstances of his home being unfavorable for suitable treatment, Dr. Tobay, who first saw him, advised his being sent to hospital. On admission it was apparent that the case was one of extreme severity, and, as it happened, the man survived only four days. Yet, it may be remarked, that with a pulse of 140, respiration reaching, and sometimes exceeding, 50, dry and brown tongue, with restless delirium, but as yet no signs of actual sinking or collapse, and death four days off, the highest temperature was 102.4°. During the succeeding days it never exceeded that point. The observation may be added to many others of a similar kind, showing that temperature is of itself a fallacious guide in pneumonia. It is not necessary to enter into details of the man's daily progress. On the first day signs of consolidation of the upper lobe of the left lung were noted as well as increased area of heart dullness. On the second day a loud pericardial friction was heard at the base of the heart, a rubbing increased in intensity by pressure, the heart's apex impulse being imperceptible. Insomnia, delirium with hallucinations, breathlessness, and such weakness that on one occasion (three days before death) the patient fainted on being gently raised for examination, were so many symptoms showing clearly enough an extremity of peril which could only admit of hope in consideration of the nature of the disease, and the absence of any physical signs denoting the breaking up of the inflamed lung. Early in the morning of the fifth day, counting that of admission, the man died, mainly by asthenia. The treatment had been by means of nutrients frequently given, with brandy in varying doses, but both food and stimulants were swallowed with great difficulty; and, as in many other fatal cases, we experienced the practical difficulty—too little considered until actually encountered—of putting in force all that was meant by the late Dr. Hughes Bennett by the term "restorative treatment." The condition of the organs found after death I now show you. A consolidated upper lobe of the left lung; hepatization passing into grey, but with no sign of softening, and no disorganization of lung tissue. The rest of this lung is barely congested, and the right lung is healthy. The heart is slightly hypertrophied as to the left ventricle, and the valves natural, but over the whole anterior surface it is covered, as you see, with shaggy and coherent lymph, which can be easily stripped off, exposing old fibrous thickening of the pericardium proper, while beneath this, again, is a layer of adipose tissue. The muscle of the heart is very soft, and in places there is nuclear excess between the muscular fibres, but on the whole the tissue is fairly normal. The right ventricle is one-fifth of

an inch thick, the left three-fifths, and the weight of the heart is 11½ ounces.¹ Both the pericardial sac and the left pleural cavity contained about ten ounces each of turbid fluid. There was no disease of any other organ, and especially it must be mentioned that the kidneys were normal.

Here then is an ordinary idiopathic pneumonia, not very extensive, not purulent, and occurring in a young and active man; yet it ends fatally, owing, as we must suppose, to the pericarditis which accompanies it. This concurrence of pneumonia and pericarditis claims attention, as I have said, on many grounds; it has a special significance in relation to the pathology of pneumonia, it lessens considerably the prospect of recovery, and in so doing it raises afresh the question of treatment, inasmuch as the great law of spontaneous recovery, which makes most of us content to leave pneumonia undrugged, no longer seems to apply.

Pericarditis is not very uncommon with simple pneumonia. Out of seventeen examples illustrating the very unusual occurrence of death in the latter disease (all the instances of the kind I could gather from twenty years' post-mortem record at St. George's Hospital²), as many as five had pericarditis and two others accumulation of fluid in the pericardial sac. This pneumonic pericarditis, unlike the rheumatic, has no concurring endocarditis; it seems like a mere extension, by a sort of sympathy, of the pleural inflammation to the neighboring serous membrane. The ordinary features of the pneumonia are not thereby changed, except, indeed, as to the chances of recovery, while, in many instances, the existence of pericarditis is undiscovered, and probably undiscoverable.

Clinically speaking, it must be remembered that both the recognition of pericarditis and the determination of its age are precarious and uncertain. The lung inflammation we detect at once, and follow easily from stage to stage; but a friction-sound is not a necessary sign in pericarditis, and may indicate either the advent of the inflammation, or such decrease of its fluid as suffices to bring the inflamed surfaces together. In the case before us friction was not audible until the second day after admission; yet post-mortem examination made it quite certain that the pericarditis was of much earlier date. In a young man under my care some years ago in the same ward, a case very similar to this one, friction rub preceded the pneumonia by nearly three weeks; it then subsided; reappearing, however, shortly before death, which was due (as examination showed) to a simple pneumonia which had lasted six days. Had this patient been admitted late, like the other, it is easy to see how the second occurrence of rubbing might have been misunderstood.

You are not to think from these two cases that pneumonia with pericarditis is commonly fatal. Far from it. It is a specially evil factor, for reasons that we shall see. To what degree it diminishes the prospect of recovery I am not prepared to say; but, on the whole, I think that pericarditis along with pneumonia is more conspicuous for its tendency to lengthen out the latter disease, and so to deprive it of the quick convalescence which is one of its striking characters, than for its tendency to end fatally. Curiously enough, the very last case of pneumonia admitted under my care before this one I am speaking of was an illustration of this. A girl of seventeen (Fanny S—, Harpur ward), in the course of a most characteristic pneumonia, showed signs of pericarditis, first by increased area of cardiac dulness, and next by fric-

tion-sound; and although the proper crisis happened on the seventh day (being the fourth from admission) convalescence was not established until three weeks later. Yet the girl made a complete recovery under treatment such as I have described.

Pneumonia seen in this connection has a special interest pathologically. The occurrence seems to supply an additional argument to the many others that have been adduced to favor the belief that the affection we call by this name is something more than a mere lung inflammation; rather that it is a complex morbid condition not limited to any one organ and having elements of danger away from the part which is the chief seat of its activity. Pericarditis is a secondary, not a primary, affection; it is known to us chiefly in connection with acute rheumatism and septicæmia, yet it may be the very first sign of an inflammation which we take pains and use names to describe as primary and idiopathic, and which, moreover, puts in a distinct claim to be so regarded, not only on anatomical grounds, but also from its habit of occurring with almost unexampled suddenness to previously healthy people.

But more to the present purpose is the question of treatment. Here is a patch of lung consolidated, as you see, by recent inflammation, yet not structurally altered. The condition is not one which would of itself be fatal. From what we know of pneumonia we are justified in saying that death was due in large measure to the pericardial inflammation. The question then arises, What is the proper treatment for this form of pneumonia? We have two acute inflammations side by side; that which concerns the lung we are taught to regard nowadays as an affection which is to be nursed and fed rather than drugged; but pericarditis is an inflammation which, even according to authors who are the least in love with medicinal treatment, needs active remedies, bloodletting, counter-irritation, and opium, for its recovery. We are thus placed in a real dilemma, for by no exercise of ingenuity can we obey two opposite sets of indications. Pneumonia is to be treated in one way, pericarditis in another; as to the treatment of the two in combination, authors are mostly silent. It is legitimate, therefore, to consider the question for ourselves and by the light of nature. What the books say or imply is this: Pneumonia has a tendency to recover and exhibits that tendency most when left to itself; but pericarditis has no such tendency; it stands in need of remedies, of the very remedies, as it happens, which are now discarded as worse than useless in the case of pneumonia. If that doctrine be true; the difficulty of treatment in such a case as the present seems insuperable. But is it true?

Call to mind the course and the termination of any examples of pericarditis you may have seen. The affection is so closely connected with acute rheumatism that you will probably think of a case of that kind. And what happens there? As everyone knows it is this: first, there is a friction-sound heard at the heart's base; next, this rubbing ceases and you get instead signs, obscure or manifest, of the presence of fluid in the pericardial sac; by-and-by, with the disappearance of these signs, friction is again audible, until, this ceasing, the sounds of the heart come out once more clear and distinct, but, probably, with a systolic murmur. Such signs, as you very well know, indicate to us the ordinary course, the natural history, of rheumatic pericarditis. They tell us of the pericardium, at first inflamed, presently bathed in a fluid which both serves as a fomentation and secures the two surfaces against the pain of rubbing or the danger of sticking, and next of the absorption of that

¹ The above description is taken from the Report of the curator and pathologist, Dr. Hebb.

² Natural History of Pneumonia, Append D., p. 296.

fluid and, so far as the pericardium is concerned, the end of the inflammation. This, I say, is the common course of pericarditis; and how can we usefully interfere with it? What do you want? It is true, unfortunately, that this is not all, especially that in rheumatic pericarditis it is not all. While we are bleeding and blistering in some sort of protest against this exocardial noise, and influenced not a little by the loudness of it, there is going on within the heart, unheard, unfelt, often unthought of, a process of change almost certain to be permanent, and of which you get the first notice at the moment you are congratulating yourself on the success of your "active treatment." Rheumatic pericarditis, as the herald of mischief to the cardiac valves, is formidable enough no doubt, but as for the exocardial part of it, I am content to leave that alone; its natural course is towards recovery, and although it be true that adhesion, hydropericardium, and myocarditis are occasional consequences of pericarditis, I am not informed of any method of treatment calculated to prevent these disasters. My chief care and thought, so far as drugs are concerned, is for the non-recovering endocardium, and the more so because the noise outside prevents its speaking for itself. It is always legitimate, therefore, to ask for remedies in *rheumatic pericarditis*, not on its own account, but because of the valve inflammation, of which it gives warning, an inflammation whose natural course unchecked is the very reverse of beneficent.

But pneumonic pericarditis is unlike the rheumatic in that there is not the same sympathy on the part of the endocardium. The sanction for drugs, therefore, arising out of the jeopardy to the valves, which the rubbing implies in acute rheumatism, is absent. What then! is pneumonic pericarditis to be left to itself? I am bold enough to think so until someone will tell me explicitly what good he hopes to do—what kind of beneficial change, I mean, he thinks to produce in the inflammatory exudation—by what is called active interference. Pneumonia tends to recovery, and so does pericarditis; that tendency may be thwarted in several ways in both cases, and in the case of the last most, but it is equally apparent in both.

But, you say, pneumonia combined with pericarditis is apt to end fatally. Yes, but why? Not because of the pericarditis, but because of what pericarditis entails. Look at the specimen now before you. Here is an inflamed pericardium, not adherent (there was just fluid enough to keep its surfaces apart), not purulent, not greatly harmful in itself, but comparable in its course and origin as well as in its microscopic characters to the inflammatory exudation of simple pleurisy. But its situation makes all the difference. The chief clinical features of pericarditis, and that which constitutes its immediate danger is the cardiac weakening it produces. Hence it is that dyspnoea, faintness, and the sensation and aspect of "cardiac anxiety," are common symptoms of the disease; hence, also, it is apt to be fatal by way of syncope or asthenia, and has for its frequent consequence, where death is delayed, pulmonary oedema. This cardiac weakening is due, no doubt, in many instances, to muscular degeneration, fatty or fibroid, the sequel of a myocarditis which is itself due to the pericardial inflammation. But not seldom before this change has taken place, at the very outset, indeed, of pericarditis, its effect upon the action of the heart is apparent; and the more so when from any cause the organ is already embarrassed. Why that should be I need not discuss here; that it is so every clinical student will admit.

Well, then, if weakening of the heart, and es-

pecially of the right ventricle, be the consequence—the invariable consequence, we may say, more or less obvious, according to circumstances—of pericarditis, and its most present danger; if syncope and asthenia and pulmonary stasis are favorite modes of dying in that affection, what morbid condition is there that we should sooner avoid in such a disease as pneumonia? Consider how in pneumonia all the strain, so to speak, falls upon the right heart and the right ventricle; how its prognosis, and treatment, and varying fatality depend upon that cardinal fact. Ought we to be surprised, then, to find that pericarditis is an especially evil associate for pneumonia, inasmuch that, other things being equal, its presence or absence makes all the difference between life and death? In speaking of pneumonia, as is now the custom (and the truth under our present mode of treatment), as a disease that commonly recovers, we are not to forget that it is always perilous. It habitually recovers, it is true; but barely so—it has nothing to spare. And just as the old treatment by semi-starvation and bleeding often sufficed to kill it (as we have the strongest grounds for believing), so likewise may the untoward occurrence of pericarditis. But there is nothing in this to give sanction to blood-letting and blistering the surface of the chest. We are told, indeed, that the effect of loss of blood is to produce the very degeneration which pericarditis is apt to produce; but with our school of therapeutics, at all events, that is no indication for such treatment. That death was inevitable in the present instance it would be rash to say. But such cases will die occasionally with every advantage of early treatment and skilful nursing, and we see the reason why. Pericarditis occurring along with pneumonia makes the prognosis more grave; it may modify some of the symptoms, and even require special treatment for some of them (as, for instance, when the pain is severe or when that restless delirium occurs which was a feature in our present case), but the inflammations are similar in their course and progress; both tend to recovery, and in both, so far as we know, such recovery is best promoted by precisely similar means. There is no reason to suppose that the several dangers which beset the two morbid conditions respectively, and which need no doubt appropriate treatment as they arise, may be escaped in the one case any more than in the other by active measures, or that what are called the indications for treatment in pneumonia are at all disturbed by the concurrence of pericarditis.

And, indeed, it is difficult to understand how and why in the general revolution of belief which has finally disposed of the doctrine that blood-letting, and blistering, and other "antiphlogistic" treatment can arrest the course of inflammation, pericarditis should have escaped any more than pneumonia. For this question is no longer one of argument derived from the natural history of disease; it is matter of experience. And in this, as in other respects, the two affections stand very much on the same level. Both were selected for bleeding and mercury at the same time and for the same reasons, and with similar disastrous results. Bouillaud, who fifty years ago was "jugulating" pneumonia, was jugulating pericarditis also, and he lost six patients out of eighteen in the process. Even Sir Thomas Watson, although he bled less, was yet more emphatic in commending the "free and unsparing use of mercury, so as to get and to keep the gums sore." And if you read his lecture as he spoke it (not, I suppose, as modern editions give it), you will see that under such treatment pericarditis was a much more formidable disease than it is now.

It was the firm "conviction" of that great physician that when the to-and-fro sound had manifested itself the patient would either die outright, or else survive only for a time, and at the expense of an adherent pericardium. If that is far from being our experience now what is the inevitable inference? There are, I repeat, occasional symptoms in both pericarditis and pneumonia which may call for the lancet, for counter-irritation, for digitalis. I do not now speak of these; but for the rest, we may say with confidence that just in proportion as antiphlogistic treatment has relaxed, from the practice of Bouillaud to the shadowy thing of to-day with its exceptions and reservations, so has the complexion of acute disease altered for the better, and that this observation, applicable especially to pneumonia and pericarditis, is as true of the one as of the other.

Original Papers.

REPORT UPON AN OUTBREAK OF TYPHOID FEVER AT NEWTON-HEATH, MANCHESTER.

By HENRY TOMPKINS, M.D., B.Sc., Etc.,
Medical Officer to Monsall Fever Hospital.

TOWARDS the latter end of last year it came to the notice of the health authorities of the township of Newton-Heath, a populous suburb on the northern side of Manchester, that cases of typhoid fever were occurring in their district much in excess of what was ordinarily to be met with, and as no sufficient cause was discovered for the outbreak, and as there was also some doubt whether all the cases met with were really cases of typhoid fever, I was requested by the authorities to make an investigation thereof, and to discover if possible to what the outbreak was due. My inquiries extended from Nov. 24th to Dec. 12th, up to which time I was able to establish the existence or pre-existence of about sixty cases of undoubted typhoid fever, so that there was no doubt about the presence of what may be called a small epidemic of that disease. The next and more important step was to endeavor to ascertain the origin of this outbreak. Up to the third week in October the district had been free from typhoid, during the next six or seven weeks sixty cases had arisen. The township of Newton-Heath extends some two and a half miles from south-west to north-east, but the bulk of the cases were situate in a comparatively circumscribed area, within a radius of some two hundred and fifty to three hundred yards; the number of cases occurring beyond this in other parts of the township did not exceed what may be ordinarily looked for at this season of the year in all large centres of population, or what were occurring at the same time in other parts of Manchester and Salford. The problem therefore to be solved was, To what influence had those residing in the above area (and which for convenience may be called "the infected area") been subjected to which those distant therefrom had not been so subjected? Attention was first turned to the water-supply, but as this is supplied from the Manchester mains and was at the same time being supplied to other districts from the same main, where no typhoid had attracted attention, this could not be suspected of having played any part in the outbreak. The milk-supply was next considered, and to this especial attention was paid, as it had been thought highly probable by some residing within the district that this might be the

origin of the whole mischief. The facts ascertained in connection herewith were as follows. In the thirty-three houses in which typhoid was present the milk had been obtained from twelve different sources, one milkman upon whom suspicion fell having supplied twelve houses entirely and three partially, but some of the most severe cases were in those houses not supplied by him; and, further, among his customers outside the above area typhoid did not prevail. Inquiry also at the farm whence the milk was obtained in no wise served to show that there was any reason to suspect that the milk was contaminated. This therefore afforded no satisfactory explanation, nor gave the desired clue. The sanitary arrangements of the district in question, speaking generally, were good. The houses are comparatively new. The excreta, etc., are disposed of in the manner known in Manchester as the pail system, and, together with the ashes and other refuse, are removed weekly. In almost every instance complete disconnection between the houses and the sewers had been effected—in fact, the entire sanitary surroundings were much better than in other and older parts of the township where typhoid was not prevalent. From the officials of the local board I elicited the following facts. About the middle of September, owing to some suspected defects in a sewer running down a main street situate in this locality, known as Ten Acres-lane, an inspection was made, and it was discovered that the level of this large sewer, eighteen inches in diameter, was defective and altogether at fault, that it could not empty itself, and was found to be more than half full of stagnant decomposing sewage deposit, that it was unventilated, and was choking up and interfering with the proper flow down the branch sewers from the adjacent streets which ran into it. To remedy this it was opened throughout its whole length, taken up, and relaid at a lower level, with sufficient fall, the final closing not taking place until the first week in November, or about the time when the first cases were brought under the notice of the board, and from which time they continued for the next few weeks to increase rapidly.

From careful inquiry I was able to ascertain with tolerable precision that the first case to come under observation occurred about the second week in October. It is pretty well agreed that the average period of incubation in typhoid fever is about three weeks. Now what do we find here? We have the opening of a defective sewer and the disturbance of a large quantity of stagnant sewage matter, in a previously healthy locality, followed within two or three weeks by a series of cases of typhoid, the earliest of which broke out in the street in which the sewer was laid, some of these being among the most severe cases met with during the outbreak, and amongst which the earliest fatal cases occurred, and during the three or four weeks following the final closure of this sewer fresh cases continued to arise, and not until that period had elapsed was there any marked decrease in the number of cases met with. Another point noted was that a larger number of cases lay to the north-east of this sewer than in any other direction; the smaller side streets running off from the main street (Ten Acres-lane) on either side in a north-easterly direction on the one-hand and south-west on the other. It was shown by meteorological observations taken in the township that in the fifty-seven days during which the sewer was open the direction of the wind was, in forty-four of those days, from the west or south-west; this would carry the infected air in that direction where the greater number of cases were found. Not that I consider it necessary to lay much stress upon this point, but we know so little as to the properties or

powers of life of the contagium of this disease, that we are not justified in saying that air laden with the poison cannot be carried even greater distances than would appear probable in this case without having its infective properties destroyed.

In *THE LANCET* a short time since notice was made of a report of an outbreak of diphtheria in the Holbeach Rural district, where the possibility of conveyance of infection by wind currents was considered. Other epidemic diseases have long been thought to travel considerable distances by the medium of wind and air currents. But no doubt most of the patients who suffered during this outbreak, living in the immediate neighborhood, would have come into close proximity to this open sewer some time during the eight weeks it was under repair, so that the wind theory is not necessary to account for them. In four houses, containing six cases, situate some considerable distance beyond the limits of the "infected area," the patients had all been for a greater or less length of time in the immediate neighborhood of the open sewer. Two of these had lived in the street in which the sewer was open, two had attended school for several hours daily within the infected area, one had visited at the house of a friend there who lay ill with typhoid, and another had passed daily to and fro by the open sewer.

Taking into consideration the whole of the above evidence there appears to be every justification for connecting the outbreak with the disturbance of this stagnant, unventilated sewer, at a period of the year too when typhoid is most prone to prevail; and although there is nothing new in this conclusion, other outbreaks of a precisely similar nature having been met with by other observers, it yet serves once more to show the danger to be apprehended, and guarded against, when defective drains, especially if containing stagnant decomposing matter, are to be opened up and disturbed.

Manchester.

CASE OF TRIPLE BIRTH FOLLOWED BY PUERPERAL ECLAMPSIA.

By PERCY BOULTON, M.D., M.R.C.P. Lond.,

Physician to the Samaritan Free and Queen Charlotte's Hospitals.

On Sept. 21st I was asked to see A. O—, who had been delivered the day previously of triplets, and was in strong convulsions. Excepting its plurality, the labour had been normal. The large single placenta had come away naturally, and the uterus contracted well without any excessive hæmorrhage. The patient was with difficulty kept in bed during the fits by two women in attendance, and in spite of a clothes-peg, which had been used as a gag, she had bitten her tongue badly. She was pale, unconscious, foaming at the mouth, the pupils were dilated, the skin cool, and the legs much swollen. I was told that before the fits she had complained of severe headache, and that she had passed very little urine. In addition to the increased arterial tension during pregnancy, the enormous size of the uterus during triple pregnancy causes pressure on the large abdominal vessels, on the bladder, thereby diminishing its capacity, and to some extent on the ureters, preventing free escape of urine into the bladder—all tending to renal congestion and uræmic eclampsia.

This patient, however, had no symptoms of convulsions till after confinement, when the pre-existing pressure had been removed, and therefore it was a question whether the fits were uræmic or not. The swollen extremities showed that although

direct pressure had been removed, the circulation had not recovered itself, and it is probable that the immediate result of delivery is to add to the troubles of renal incompetence, since diminished centrifugal flow towards the uterus would increase pressure on the renal arteries, and the products of involution charge the circulation with matter which would cause irritation and contraction of arterioles, and so further increase arterial tension. The cold pale surface and dilated pupils pointed to superficial and cerebral anæmia from this cause, while the kidneys were in a state of active hyperæmia and the urine highly albuminous.

The treatment which I ordered was that the loins should be constantly poulticed, and that she should take directly a strong jalap purge, and twenty grains of bromide of potassium every three hours, the diet being restricted to milk. When I next saw her I was prepared to give a hypodermic injection of pilocarpine, which is a valuable remedy in such cases, causing profuse perspiration, with excessive excretion of urea. The girl, however, was so much better that she continued the former treatment with the very best results, and is now quite convalescent. Theoretically nitro-glycerine, or amyl nitrite, so valuable in exalted reflexes, should be of service in such a case. In my experience they cause dilatation of the contracted arterioles, and have decidedly a temporary, but no permanent, good effect.

Seymour-street, W.

ON RETRACTION OF THE FLAP AFTER SYME'S AMPUTATION.

By BENNETT MAX, B.S.

AMONG the morbid conditions of stumps there is one incidentally alluded to by Mr. Savory in his "Notes on Surgery," which appeared in *THE LANCET* last month. It is that of retraction of the heel flap after Syme's amputation. Although not generally recognized or looked for, it is as he points out, a contingency to be provided against in certain cases, of which an example is now under my care at the Queen's Hospital. The patient is a young man on whom I performed a double amputation for a railway smash eighteen months ago, removing one limb below the knee and the other at the ankle. He made a very quick recovery, and for some time was very comfortable, but a few weeks ago he came to show me his Syme's stump, on which he was no longer able to bear any weight owing to the pain this gave him. I found that he was walking on the cicatrix, where two large painful corns had developed, and that the heel flap, instead of receiving all the pressure, was retracted quite to the back of the leg, the integuments above it being thrown into several transverse folds from the laxity. It had evidently been drawn into this position by the muscles of the calf. Fortunately a division of the tendo Achillis has completely liberated the flap, and has enabled me to readjust it and replace it in normal position with complete relief to his troubles. I explain the occurrence in this case—1st, by the fact, that the operation being a primary one, the muscles of the calf were caught in a state of full development and activity, and not attenuated by long disuse; and 2nd, that owing to the rapid recovery which took place the tendo Achillis at a very early period attached itself to the heel flap—obviously a disadvantage, and one which I should endeavor to prevent in a future primary amputation by severing the tendon some distance above its insertion into the os calcis, or by removing an inch of it after division. The operation was origin-

ally performed almost precisely on the lines recommended by Mr. Savory, at least in the one particular of carrying the incision right across the sole and not backwards.

Birmingham.

ON A PROLONGED CASE OF TETANUS.

UNDER THE CARE OF

Dr. J. ROBINSON and Mr. STENSON HOOKER

Reported by the latter.

W. H.—, aged fourteen, on May 31st last, whilst bathing, received an incised wound on the ball of the great toe by treading on a piece of broken bottle; all went well until June 9th, when he complained of a "cold in the jaw," with stiffness of the muscles of the neck and between the shoulders; the wound was now healing nicely.—June 10th: The jaw is all but closed, and the muscles of the abdomen, back, and limbs contract still more strongly when touched. The urine is loaded with lithates; bowels rather confined. He takes liquid nourishment well, this being accomplished by suction, the teat of an infant's feeding bottle being squeezed between the teeth. Temperature 101° 6'; pulse regular, 100. Given twenty grains of bromide of potassium every four hours.—11th: There is general clonic spasm of all the voluntary muscles with intense pain; at times the condition is that known as opisthotonos. Given a scruple of chloral hydrate. Temperature 102° 2'; pulse 160.—12th: Pain and muscular contraction still intense. Chloroform was administered, which relaxed the muscles and gave him sleep, but immediately on awakening the rigidity recurred. This extreme state continued, Chloroform being administered each day until the 23rd, there being no cessation from spasm except when under the influence either of this drug or of opiates.—20th: Continues to take nourishment well; this consisted of milk, soup, and beef-tea. Temperature 100° 2'; pulse 100. The bromide was evidently useless, and was therefore discontinued.—23rd: Five drops of tincture of Calabar bean were given every two hours; the dose was increased gradually day by day. Wound healed. Pulse 116; temperature 100° 2'.—26th: There is some loss of vision, which is hazy; he cannot distinguish objects further than a yard off. Pulse 124; temperature 102° 4'. Is now taking twenty drops of the drug every four hours.—27th: There is complete loss of vision; pupils are normal. He is slightly delirious, and complains of tingling in both feet. There is no natural relaxation of the muscles. Pulse rather smaller, regular, 120; temperature 102°.—30th: The spasms are a little less violent and less frequent in the muscles of the trunk. He is now taking thirty drops for each dose. The vision has returned to some extent. Urine copious; bowels rather relaxed. Takes nourishment well. Pulse 94; temperature 100°.

July 3rd: The spasms are not so violent, and are confined to the lower extremities. He is now taking sixty-five drops every four hours.—4th: The masseters relax slightly, and there is a constant desire to yawn.—9th: Patient can now flex both arms, also the leg upon the thigh. Temperature 98° 8'; pulse 96.

There was a slow improvement from this time, the intervals between the spasms becoming more and more prolonged. On the 12th he could eat solid food for the first time since the attack; and on the 31st he could eat and talk fairly well; there was no spasm, but the legs were still somewhat rigid. On Aug. 5th all rigidity had disap-

peared, and the Calabar bean was omitted. The patient was up on the 7th and complained only of general stiffness and debility, and from this date he gradually recovered and now enjoys perfect health.

Remarks.—The interest in this case lies in its exceptional prolongation. Twenty days passed before the slightest cessation of spasm took place, twenty-four before the muscles even commenced to relax, while fifty days passed before there was absolute freedom from spasm and rigidity. This I believe to be the longest case on record, and the question which suggests itself is, Did the drug, Calabar bean, exert any influence for good in this case? It will be seen that it produced, at least, physiological effects which are unusual, if not unique, the patient being for three days totally blind.

Midhurst.

ON A CASE OF SIMPLE FRACTURE OF THE STERNAL END OF THE CLAVICLE INTERNAL TO THE RHOMBOID LIGAMENT.

By G. OWEN WILLIS, L.R.C.P., L.R.C.S. Ed.,

Senior Surgeon to the Monmouth Hospital.

J. E.—, aged fifty-four, a laboring man, was admitted into the Monmouth Hospital on July 18th, 1881. He stated that two hours previously he slipped off a hayrick, fell heavily on his outstretched right hand, and also struck his right shoulder. On examination a simple fracture of the sternal end of the right clavicle was discovered within a quarter of an inch of the sternal head of the bone. The direction of the fracture was obliquely downwards and outwards. The outer fragment rode high in the neck from the action of the clavicular fibres of the sterno-clavicular mastoid muscle and the weight of the arm. The fractured end of the outer portion was very sharp, and threatened to lacerate the skin. The inner fragment presented no marked sign of displacement, was freely movable, easily depressed, and on pressure the sensation was conveyed to the finger of its being loose and rolling. He had fractured the sixth and seventh ribs in front of and close to their angles. My efforts to adapt the broken ends of the clavicle were but partially successful. Apposition of the ends was gained when the right arm was raised and the fingers of the right hand touched the left ear, the point of the elbow being slightly tilted forwards by a pillow. Any attempt to fix the limb in this position was not tolerated for long. I had to content myself with slinging the arm and placing a pad of cotton-wool on the shaft of the clavicle; this last kept in position by strips of plaster crossing the chest from back to front. He had a sharp attack of pleurisy, and was very restless, often getting in and out of bed, but recovered and was discharged convalescent on August 29th, 1881. I saw him again on August 30th, 1882, when a photograph and cast were taken. The broken end of the outer fragment was rounded off and lessened by absorption, and he had fibrous union permitting of some movement. That morning he had done a bit of stiff digging, and considered his recovery a good one.

I have been influenced to publish this case at such length because fracture of the sternal end of the clavicle is rare, whilst fracture internal to the rhomboid ligament is very rare. Holmes, in his "Principles and Practice of Surgery," 1875, says, "it has not as yet been proved." Bryant makes no mention of the injury, and I am indebted to

the kindness and courtesy of my old teacher, Mr. Henry Morris, of the Middlesex, for the following references:—Hamilton refers to three cases (in a record of 105 fractures of the clavicle) in which the fracture was within one inch of the sternum, and he says that in such fractures, which are, of course, within the fibres of the rhomboid ligament, there is but little displacement. Lonsdale mentions a case in a child three years old, which came

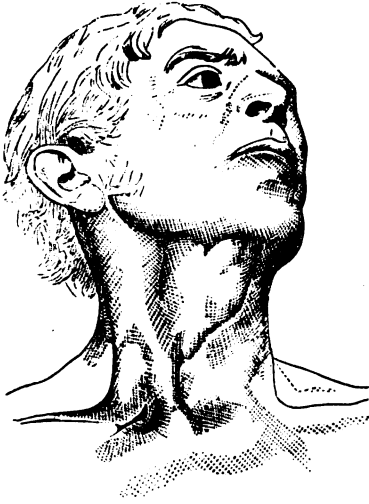

Fig. 1.

under his care in the Middlesex Hospital, and which he regarded as a separation of the epiphysis. Malgaigne mentions two cases, in one of which the fracture was so near the sternum that it was difficult to say whether it was not a partial dislocation; the displacement was only trivial. There are two preparations in the Musée Dupuytren, in Paris, of fractures very close to the sterno-clavicular joint, and in both the displacement is considerable, and in both the outer fragment is thrown down and forwards. Hamilton, in a recent edition of his work, says he has had a case of fracture

Fig. 2.

close to the sternal end, the specimen of which he showed to the New York Pathological Society. The man from whom the specimen was taken was forty-five years old, and the fracture, occasioned by a fall upon the shoulder, extended from the sterno-clavicular articulation upwards and outwards an inch and a half. The fragments were over-lapped three-quarters of an inch, and were firmly united.

(27)

The character of the accident was not recognized until after death. The specimen is now in the Bellevue Hospital. In the case I report there can be no doubt that the rhomboid ligament was ruptured, and it was remarkable that the displacement of the outer fragment, which was very considerable, was upwards and not downwards, as in the cases collated by Mr. Morris.

Monmouth.

ON A CASE OF OVARIOTOMY AT THE AGE OF SIXTY-ONE.

MULTILOCLAR CYSTIC TUMOUR OF THE RIGHT OVARY;
REMOVAL; RECOVERY.

By A. C. BUTLER SMYTHE, M.R.C.P., F.R.C.S. Ed.
Surgeon to the Farringdon General Dispensary and Lying-in Charity.

Mrs. M—, aged sixty-one, widow, married at twenty-nine, has had six children, the youngest being twenty-one years of age. First child still-born, all other labours natural. Menses appeared at fifteen, ceased at forty. Has never been very strong. Her mother died of "cancer of the liver." About twelve months ago she noticed herself getting large and thought she was gaining flesh; later on, owing to gradual increase in her size, the swelling being uniform and painless, she believed she had "the water." Within the last six months she lost flesh rapidly, and complained of difficulty in passing water, and of pressure over the bladder, together with forcing down pains. These symptoms caused her to seek advice, and she came to me. She was very emaciated and anæmic, and her features presented that peculiar pinched expression, the "facies ovariana," described by Mr. Spencer Wells. On examination I found the abdomen much distended, with dullness over the anterior surface, and resonance in flanks. Fluctuation could be distinctly made out, and the aortic sounds and impulse were transmitted. Per vaginam the uterus was found to be retroflexed and low down in the vagina, and the base of the tumour could be felt on the right side. The diagnosis was tumour of the right ovary, multilocular, and chiefly fluid. I therefore determined to operate without delay.

The operation was performed on Sept. 13th, 1882. Chloroform being administered, I was about to commence, when the patient vomited several times, and in a few moments became pulseless. Some time elapsed before she was brought round. As it seemed dangerous to go on with the chloroform, ether was proposed, and administered without the slightest inconvenience, both pulse and respiration at once improving under its influence, and the vomiting ceasing. Carbolic spray being carefully directed over the abdomen, I made an incision about five inches in length, and opened the peritoneum on a director. The cyst was fairly movable, there being but two or three small adhesions to the abdominal wall on the right side. I punctured the larger cyst and drew it forward, and, having emptied several smaller ones, found that the lower part of the tumour was held down by some strong bands, stretching to the right side of the pelvis; these gave some trouble, and I had to enlarge the opening. Having separated them, the tumour was extracted. I then transfixed the pedicle, which was very thin and broad, and tied it in two halves, not crossing the ligatures, and put on another ligature for safety, between these and the uterus. The left ovary was enlarged to the size of a walnut, but as there were no cysts I left it alone. There was very little bleeding, and

no fluid escaped into the peritoneal cavity (thanks to Mr. Dewar, who ably assisted me). Having sponged carefully, I closed the wound with carbolized silk ligatures, and applied Lister's dressings. The tumour weighed over 19 lb., and contained a brownish-colored fluid and colloid matter.

The patient did well and had no sickness or cough whatever. On the third day she had beef-tea by the mouth, and on the fourth she was moved into another bed, this treatment being continued about every third day throughout the case. The sutures were removed on the eighth day, when the wound was found to be firmly closed. On the twelfth day she complained of headache and chilliness, when the temperature suddenly rose from 99° to 103·6°, and the pulse from 80 to 116. She had no abdominal pain, but her urine was highly concentrated and loaded with urates. On examining the wound I found a suture had been overlooked; this was removed and ten grains of quinine and twenty minims of tincture of opium ordered to be administered per rectum, and repeated in three hours. Thornton's ice cap was also put on. On the next day (the thirteenth) the temperature had fallen to 99°, pulse 84. From this date the patient's progress was most satisfactory. On the sixteenth day the bowels acted, by the twenty-fourth she was sitting up in bed, and on the twenty-eighth she was able to walk. From the first the bladder was troublesome, and the urine at times loaded with pus. I treated this condition by washing out the bladder occasionally with warm water, and gave twenty-minim doses of tincture of perchloride of iron three times a day. It was exactly one month from the date of operation before the patient had complete control over the bladder.

Remarks.—In this case I adhered strictly to the rules laid down by Mr. Spencer Wells, with the exception of the anæsthetic. I also adopted his suggestion of using two small iron bedsteads for the purpose of changing the patient occasionally. This was found to be most agreeable to the patient, who after the first removal, always reminded us if we had forgotten to change her. The sudden rise of temperature was undoubtedly caused by the suture which I had overlooked setting up some septic mischief. All ligatures used at the operation were previously boiled in a 5 per cent. solution of carbolic acid. The stimulant given was brandy, and this only in small quantities, not more than six ounces being used throughout the case.

Feb. 12th, 1883.—At the present date the patient is in perfect health, and able to attend to her household duties.

BOROGLYCERIDE IN THE TREATMENT OF PURULENT OPHTHALMIA.

By GUSTAVUS HARTIDGE, F.R.C.S. Eng. etc.,
Assistant-Surgeon to the Central Ophthalmic Hospital.

I HAVE for several weeks tried the effect of boro-glyceride in a few cases of purulent ophthalmia which have come under my care at the Central Ophthalmic Hospital, and although the number I have treated is much too small on which to form any definite opinion, still the results have been so encouraging that I am induced to publish them in the hope that others may make a trial of this antiseptic. I cannot but think that if its antiseptic properties were fully established, it would prove of great value for disinfecting instruments etc. in cataract and other operations where a non-irritating antiseptic is required. The way in which

I have employed it in purulent cases has been to evert the lids, and, after cleaning away all pus and secretion with cotton-wool, to brush the mucous membrane over with a 1 in 10 solution of the boro-glyceride, taking care to introduce it well under the upper lid. This has been repeated daily, and in the interval the mother has been instructed to bathe and clean the eyes and lids every hour with a 1 in 40 solution. No other treatment was used, and the cases began to improve at once, being usually well in from eight to ten days. Where one eye only was affected I have, after brushing over the lids, applied a piece of lint soaked in 1 in 20, covered with a pad of cotton-wool, and bandaged the eye, with the result of preventing the sound eye from becoming attacked. In all the cases the cornea was unimplicated.

Boroglyceride is an antiseptic introduced by Professor Barff, and has been used considerably in Germany in surgical cases, and also for domestic purposes, the preservation of meats, etc. It is made by the chemical combination of boracic acid and glycerine in certain proportions, whereby a new compound, boroglyceride, is formed.

The following are some of the advantages of this antiseptic: it is readily soluble in cold or hot water; it is odorless, tasteless, and unirritating; a 1 in 10 solution dropped into the eye causes scarcely any smarting; and, according to its introducer, it is innocuous.

Kensington-park-gardens, W.

THE CASE (ACUTE DIABETES) OF POLICE CONSTABLE SANSOM.

By W. WANSBROUGH JONES, M.B. Oxon, etc.,
House Physician, St. Thomas's Hospital.

THE main facts relating to the death of Police Constable Sansom have been fully recorded; I purpose here adding only the few clinical details obtained during his short stay in hospital.

It will be remembered that on the evening of Sunday, December 24th, he complained of feeling unwell for the first time during the two years he had been in the police force. He felt aching pains in his limbs, and too weak to do his eight hours' duty. He managed, however, to get through it, but broke down during the Monday night. On Tuesday night he was not allowed to go on duty, but sent to bed by the deputy divisional surgeon. On the Wednesday he was once a little delirious. On Thursday he seemed weak and ill, but Dr. Blades was unable to arrive at a diagnosis after going fully into the case. The urine he was unable to obtain for analysis. On the Friday morning he became semi-comatose and very collapsed, and in this condition was admitted into St. Thomas's Hospital under the care of Dr. Bristowe. Some simple restoratives were administered, and in about three-quarters of an hour he was seen by Dr. Bristowe. He was then sufficiently conscious to answer questions asked in a very loud tone of voice. He said he was not in pain, and though he answered questions put to him intelligently, very little could be gathered as to his condition. The policeman who had been taking care of him could give very little information about him, excepting that he had passed water frequently during the night. The result of a careful physical examination was equally unsatisfactory. The skin was dry; the tongue slightly furred and dry. He was thin, but not emaciated. The temperature was normal. The pupils of moderate size, equal, and reacting to light. The lungs in front, the heart, and abdomen seemed natural. There was no œdema of the limbs, and no sign of paralysis. Dr.

Bristowe therefore thought that the man was either suffering from uræmia or in a state of diabetic coma. As no water was voided during the first four hours after admission a catheter was passed, and four ounces of urine drawn off. The temperature rose, the breathing became quicker and the coma more profound, and in the course of the next hour he died. Half an hour before death the temperature was 103°; half an hour after death it was 105°.

A post-mortem examination was made on Saturday afternoon. All the viscera, including the nervous centres, were congested, and the brain seemed to have the sweet odor which is said to be characteristic of diabetes. The congestion was recent, and was in all probability due to the feeble action of the heart for some hours before death.

Remarks.—The great difficulty and obscurity of the case will be at once apparent when it is noticed that neither the examination made before death nor that after death afforded any satisfactory explanation of the patient's condition. In fact if the few ounces of urine mentioned above had not been obtained the case might still remain a mystery. This urine was of a high specific gravity—1040, acid reaction, and contained a large quantity of sugar and some albumen. No medical man looking at the whole of these facts could for one moment doubt the nature of Police Constable Sansom's malady. Nor is there anything peculiar in the sequence of events. The diabetes ran its usual course. But it was a most unusually rapid course. Diabetes is usually a very chronic disease, which kills the patient by gradually exhausting him until he falls into a comatose state, or dies of phthisis. Cases of so-called acute diabetes are very rare, and probably several of the cases so classified if thoroughly looked into would prove to be cases in which the disease had been existing unrecognized for some time, but in which some acute exacerbation had brought symptoms into prominence which led to a diagnosis. There are several cases on record in which death has resulted in two or three weeks from the first recognition, it may be the first onset of the disease. But a case of only five days' duration in a man apparently quite healthy before is to us at any rate quite unprecedented.

NOTES ON SURGERY.

By WILLIAM S. SAVORY,

Surgeon to St. Bartholomew's Hospital.

On the Treatment of Enlarged Prostate.

WHEN complete retention of urine from enlarged prostate occurs, it frequently happens that the introduction of an instrument is followed by temporary return of power to micturate; and in other cases of partial retention it is well known that the occasional passage of an instrument will for a while restore the ability to empty the bladder almost completely without help. The cause of the difficulty being a mechanical one, I suppose there can be little doubt that the introduction of an instrument does good in this way by pressing aside that portion of the enlarged prostate which is most immediately concerned in producing the obstruction. Now, much more good in this direction, and good, too, which will last much longer, is often gained by retaining a catheter for some time after it has been introduced—say for one or two hours or so, as the patient may be able to bear it without distress. This plan is well worth trying in most cases of the kind. When an instrument has been passed, whatever difficulty there may have been in its introduction has been overcome,

and the patient is subjected to little or no additional trouble by its retention for a short period. I may add that for this purpose a silver catheter appears to me to be of more service than a flexible one. It will be observed that this plan of repeatedly retaining an instrument for an hour or so after it has been passed is quite distinct in principle and purpose from the practice which has been advised, and is sometimes adopted, in cases of complete retention, or of very frequent micturition, or where there is unusual difficulty in the introduction of an instrument, of retaining it for many hours or even days together. The object here is either to escape a difficulty which may become insuperable or to avoid the necessity of passing an instrument so frequently as to make this a source of grave irritation and further mischief. Here, unfortunately, the proposed remedy is often worse than the evil. The plan now advocated has been suggested with the view of taking advantage of the passage of a catheter, when it is required to relieve the bladder, to retain it for its effect upon the prostatic portion of the urethra; for the good it does in this way of restoring or improving the power of micturition, or possibly by pressure promoting in some degree absorption. In speaking on this subject, I would add that in my experience, as in that of others, in cases even where the prostate is considerably enlarged, it is often easier to introduce a catheter with an ordinary curve than the instrument which is especially made for cases of this description. Surgeons know very well that sometimes when a prostatic catheter cannot easily be passed, an instrument with a much smaller curve will easily slip in. I fancy that the advantage on the side of the smaller instrument is more common than it is generally supposed to be. With me, at least, it is the rule; and so, to relieve the bladder in cases of enlarged prostate, I should take first an instrument of full size with an ordinary curve, or a curve not exceeding the quadrant of a circle two inches or so in diameter.

On the Treatment of Stricture of the Urethra.

It may be well from time to time to call attention to the still prevalent practice of treating all cases of stricture of the urethra by the introduction of instruments. I say all cases; for when a stricture has been once made out, does it ever escape bougies? How many cases occur of contraction due to spasm or to temporary thickening of the membrane from inflammation or congestion, which if left alone would speedily clear up, but which are worried into permanent stricture by such mischievous activity? Even when organic or permanent stricture is established, how very seldom does it come under the notice of the surgeon uncomplicated by inflammation or congestion and spasm? and are these conditions to be subdued by the employment of instruments? Is this in accordance with any recognized principle in surgery? Many cases of so-called stricture need no instrumental interference from first to last, and by such means are only made worse; and of those cases in which much may be done at the proper stage by the judicious use of instruments, there are very few indeed which do not require, for some time previously and simultaneously, treatment in the way of rest and other measures to subdue the active mischief, which in ordinary circumstances is almost invariably associated in some degree with passive structural contraction. The story is well known of a physician who, having in consultation discovered pericarditis, consoled his colleague who had overlooked it with the reflection, "My dear fellow, if you had found it out you would have treated it." How far the ordinary treatment would have been bad for the pericarditis

I cannot say; but I am sure that stricture of the urethra sometimes suffers very much at the hands of surgery from being found out; and, unfortunately, it has but little chance of escape in the way of being overlooked. In every case, of course, instruments must be passed, and the existing evil is not only apt to be thus aggravated when present, but too often it is nursed into existence.

FOURTEEN CASES OF DIGITAL EXPLORATION OF THE BLADDER, IN SIX OF WHICH VESICAL TUMOUR WAS REMOVED.

By Sir HENRY THOMPSON,

Surgeon Extraordinary to His Majesty the King of the Belgians,
Consulting Surgeon and Emeritus Professor of Clinical Surgery to University College Hospital, Etc., Etc.

At the meeting of the Royal Medical and Chirurgical Society of January 23rd last I stated that, for the purpose of diagnosis in exceptionally obscure cases of urinary disease, I had of late performed a limited incision of the perineum carried to the membranous urethra only, and sufficing to enable me to carry the index-finger to the neck of the bladder, after which, by supra-pubic pressure under complete anaesthesia, the whole of the interior of the bladder might be examined by the finger, and its condition be easily determined. I stated in my paper, in language the most distinct I could adopt, that the incisions in question had been frequently employed for two centuries at least for stricture, retention, etc., but that they had not been employed for the purpose of making the diagnostic examination above described, and, moreover, that such examination became possible only since we have had the power to produce at will complete relaxation of the patient's abdominal muscles by means of ether and similar agents; and I claimed this proceeding to be a new mode of diagnosing such obscure conditions, and also of treating them when, as has often happened, the incisions made have sufficed also to enable me to take away a tumour or other source of disease, not removable otherwise than by operation. In order to illustrate and support these statements I append very brief notes of every case in which I have made this exploratory incision, so as to enable the profession to judge of the proceeding and of its results. I have during the last two years and a half met with thirteen cases in the male of obscure disease in which I deemed it right to employ digital examination of the bladder. I add one case of dilatation of the urethra in the female, because tumour was present and was removed, this being a proceeding which may be regarded as analogous to that above adopted for the male; and I think it will be regarded as a very striking fact—to none has it been more unexpected than it has been to myself—that among these fourteen cases I have found and removed vesical tumour of considerable size in no less than six of them.

CASE 1.—T. R—, aged twenty-nine. I crushed an oxalate of lime calculus on Aug. 5th, 1880. Symptoms were very slightly relieved, and he became worse in the autumn. The condition being obscure, I operated on Nov. 6th by perineal urethrotomy, Mr. Ceely, of Aylesbury, and others, present. I found a fibrous polypoid growth (Fig. 1), and removed it with the forceps. He made a rapid recovery, and is perfectly well now and actively engaged in business. He was present at the lecture.

CASE 2.—A gentleman, aged forty-eight. Had been the subject of painful frequent micturition for several years, and of slight hæmaturia, without

obvious cause. On June 27th, 1881, I operated, finding no specially morbid condition. The tube was retained in the wound for a week. He was much relieved, and has been better ever since, although still troubled with the same symptoms, but notably less severe.

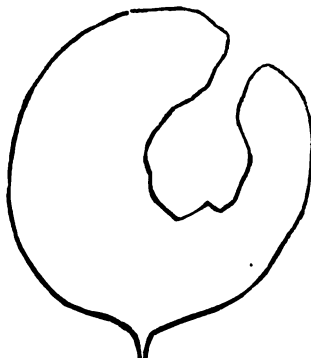

Fig. 1.

Form and situation of tumour in the bladder. (Case 1).

CASE 3.—A gentleman, aged fifty-two. I performed lateral lithotomy for a large uric-acid stone on June 1st, 1880. He made a good recovery, but was afterwards troubled with phosphatic deposits and bleeding. Nothing was found by careful search except a small concretion on two occasions; hence I operated on June 17th, 1881, removing some phosphatic deposit closely adhering to the inner coat, retained the tube a week, and then withdrew it. The wound rapidly healed, and he has been better since, but not altogether free from alkaline phosphatic urine.

CASE 4.—A gentleman, aged sixty-eight. I crushed a uric-acid calculus on March 18th, 1881. He became unable to empty his bladder from prostatic hypertrophy, and used the catheter habitually. A year after he began to lose blood daily, not from the catheter, which he used with great ease. Careful sounding failed to detect a cause. He was now very feeble, and I had the advantage of consultation with Sir W. Jenner, who agreed that exploration would be desirable. On Feb. 10th, 1882, I did this, and found closely adhering to the coat of the bladder a scale of phosphatic deposit, which I removed with the finger-nail, tying in a tube for seven days. The bleeding soon ceased, and has never reappeared. He is now enjoying better health and more activity than for a long time past.

CASE 5.—A gentleman, aged sixty, with hypertrophied prostate, who passed all urine by catheter, at the rate of sixteen times in the twenty-four hours. I operated on March 20th, 1882, retaining a tube in the wound, by which all the urine passed for seven days. The relief was remarkable. Soon after the wound healed, and the catheter was employed only six times in the twenty-four hours, while the patient's health and strength greatly improved, and has continued so. Seen with Dr. Chepmell and others.

CASE 6.—A lady, aged thirty, the subject of severe cystitis and hæmaturia at intervals for five years. I dilated the urethra and explored the bladder with the finger, discovering a polypoid tumour of considerable size (Fig. 2), and removing it with the forceps. She made an excellent recovery, the pain, frequent micturition, and bleeding, all disappearing before the end of the month. Seen with Dr. Philson, of Cheltenham. She was

reported in good health, free from symptoms, in October.

CASE 7.—A gentleman, aged seventy-two. I crushed a phosphatic stone in Feb., 1878. He passed most of his urine by catheter, and had small deposits removed subsequently. In the winter of 1881-82 his symptoms became severe and distressing, and were controlled only by morphia. Sounding detected no adequate cause. He became very feeble, and was seen by Sir W. Jenner, who assented to the operation as the best chance of relieving his sufferings. I performed the operation

very free, and continued to be so next day, and he sank before night.

CASE 10.—A gentleman, aged fifty-two, had suffered from hæmaturia about five years, with long intervals of freedom, particularly after the injection of perchloride of iron. On Nov. 13th, 1882, he reported the return of severe bleeding in July last, and more or less continuous since, with painful and frequent micturition, loss of strength, etc. On Nov. 20th I operated in the presence of Dr. George Johnson and Mr. Erichsen, finding a considerable polypoid growth springing from the left

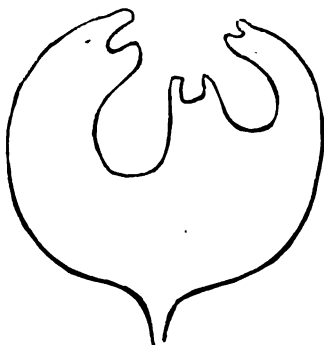

Fig. 2.

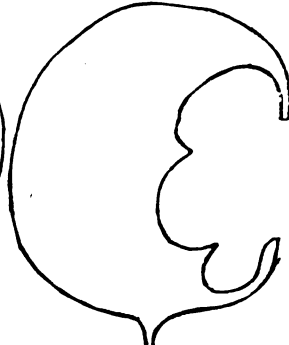

Fig. 4.

Form and situation of tumour in the bladder (Case 10).

on June 21st, 1882, and found a sac near the neck of the bladder containing a calculus the size of a large bean, which I turned out with my finger. His sufferings were completely relieved and all necessity for catheterism was avoided, but he sank soon after from exhaustion.

CASE 8.—A gentleman, aged eighty-three. Has long suffered from unusually painful and frequent micturition, the interval rarely reaching forty minutes either by day or night. He almost emptied the bladder naturally, and required his catheter once a day only; but he took morphia freely. No calculus or organic change in the urinary organs could be detected. General health excellent for his age. On Jan. 30th, 1882, I operated, finding no morbid condition, except hypertrophy of the vesical coats, placed the tube in position to withdraw the urine by, and kept it there twelve days; its presence relieved him so greatly that he was unwilling to part with it, not having been so comfortable for a year, and discontinuing the morphia altogether. The wound rapidly healed, and he held his urine from two to three hours. He continues greatly improved at the present time.

CASE 9.—A gentleman, aged forty-six. In the spring of 1881 micturition was extremely frequent. Blood appeared first in November, subsequently abundant and mixed with phosphates. In May, 1882, he came to me with Dr. Davies, of Swansea. No calculus was found, but the interior of the bladder felt thick and soft on moving the sound. Small masses of semi-translucent material, chiefly composed of nucleated cells are passed in the urine. Returned to the country; to try styptic injections. On Nov. 1st he came up with symptoms considerably increased in severity. Having no doubt that the cause was tumour, I operated on the 3rd, finding a large mass filling the bladder, springing from a wideish base at the upper part. I removed the greater part by means of the forceps, half filling an ordinary tumbler with the debris (Fig. 3). A tube was tied in. The bleeding was

side of the bladder (Fig. 4). This I removed with the lateral curved forceps. Bleeding was rather free for thirty-six hours; no pain. He made a steady recovery, and left town perfectly well in a month's time. Urine healthy, retained five hours.—Jan. 23rd, 1883: Has recently seen a trace of blood after a seven-mile walk, which he felt was too much for him.

CASE 11.—A gentleman, aged twenty-four, first seen in April, 1882, who for about two years has suffered severely from pain, frequent micturition, and bleeding. The stream often commences of the natural color and becomes bloody before ceasing. Has been sounded and treated but without benefit. After using various remedies I advised exploration. On Dec. 15th, 1882, I performed in the usual manner. There was no tumour, but the whole of the mucous membrane of the bladder was much thickened and rugose. The tube was retained about five days. Hæmorrhage continues as before, and disappears only when a catheter is tied in and retained, the urine then continuing clear and healthy. No benefit appears at present to have resulted from the proceeding.

CASE 12.—A gentleman, aged sixty-seven, saw blood in his urine six years ago, and often passed uric acid calculi. June 2nd, 1882: Lithotripsy at one sitting, removing 200 grains, Dr. Burnet present; much bleeding afterwards. The relief was slight; frequent bleeding, during autumn, and much phosphatic deposit; nothing found by sounding. He is very stout and heavy.—January 17th, 1883: Perineal incision as usual; perineum very deep; found rather firm and broad tumour, left side (patient's) of bladder. Removed by forceps with some trouble; bleeding free for two days and pain severe. Resembles Fig. 4, but less pedunculated and nearer to the neck of the bladder. Tube was removed on eighth day.—Feb. 1: No pain whatever or blood; micturition frequent.—5th: Improving; holds water longer; walks out for the first time to-day.

CASE 13.—A gentleman, aged fifty-two, from Cape of Good Hope. Painful micturition for a year past and great frequency; no cause discoverable by any examination I could make. Urine purulent, no blood. Health excellent. Much treatment before coming over without result. No relief from medicine here.—Jan. 22nd, 1883: The usual incision enabling me to explore entire surface of the bladder and finding nothing. Tied in tube, which remained eight days, during which all pain ceased, and he slept as he had not done for months; symptoms gradually improving.—31st: Took out tube; no pain.—Feb. 5th: Some pain, not severe; urine much improved; wound healed.

CASE 14.—A gentleman, aged sixty-seven (sent by Dr. W. Anderson, of Richmond), saw blood first three years ago; last four months constant hæmaturia, increasing in amount. Stream often begins clear and leaves off deep florid-red, seen by myself. Shreds in urine show tissue containing spindle-shaped cells and fibres.—Jan. 30th, 1883: Operated as usual, Dr. George Johnson and Dr. B. Sewell present, removing tumour broadly pedunculated and sessile from left side (patient's) of bladder. With some trouble extracted a large mass. Pain and bleeding not considerable. Resembles Fig. 4, but larger and broader at the base, and approaching the neck of the bladder.—Feb. 2nd: Bleeding ceased; pain slight; little feverish; pulse 96.—5th: Urine almost clear; patient doing well.

Wimpole-street.

A GROUP OF EIGHT CASES OF CANCER OF THE RECTUM.

SUCCESSFUL COLOTOMY IN FIVE; SUCCESSFUL PARTIAL EXCISION OF THE RECTUM IN ONE; TWO NOT OPERATED ON; REMARKS.

By ARTHUR E. BARKER, F.R.C.S. Eng.,

Assistant Professor of Clinical Surgery at University College, and Assistant Surgeon to University College Hospital.

THESE eight cases occurring in my own practice comparatively recently appear not unworthy of brief record as a completed group, illustrating, as they do, when contrasted, many points of interest in regard to this formidable disease, as well to pathology as to clinical history and treatment. Colotomy having been performed on four of them during the month of August last, and having operated on two others not very long before, many details connected with the procedures employed have been brought more forcibly under my notice than if the cases had occurred sporadically and the impressions regarding them as contrasted are still fresh in the memory. Besides this, it has been possible here to keep five out of the six cases operated on under almost weekly observation up to within the last month (Jan. 1883), and the condition of each has been carefully noted.

Pathologically considered, the disease in seven out of the eight cases appeared, from careful manual examination and clinical history, to be of the usual form of cancer met with in the rectum, sometimes spoken of inappropriately as adenoid, but better as columnar epithelioma. In one instance (Case 2) where excision was performed this structure was proved by the microscope. But in another (Case 5) I am inclined to think, from the history before and after operation, that the growth was probably encephaloid. In all but one the growth was seated fully three inches from the anus when first examined, and involved the whole cir-

cumference of the bowel; in one (male) it was limited to the postero-lateral aspect of the gut; in all the anus was free, and in none was there any trace of glandular or other secondary deposit discoverable; only two were females. In all there was no history of causation, and in seven the family history plainly negated heredity.

Clinically the cases differed considerably owing to the different stages of growth. Thus six were operated on respectively at twelve, five, twenty, eighteen, five, and twelve months after the first appearance of symptoms indicating the presence of cancer; the last two unoperated on were examined at two and eighteen months respectively after the same time. Blood in the motions was in four cases the first thing noticed, and was present sooner or later in all. Irregularity of the bowels, either difficulty in defecation (in two) or diarrhœa (in four), was the next earliest symptom, and "bearing-down" pain the next after this; but three patients suffered comparatively slightly from continuous pain, only complaining of a little during motions. Pain down the thighs was a notable symptom in two cases. Finally, diarrhœa, amounting to as much as twenty motions daily, became the most prominent feature in three out of five of the advanced cases. Only once (Case 1) did the growth invade neighboring organs—i.e., the vagina. The clinical factors determining or contra-indicating operation were as follows. In Case 1 the growth had opened up the vagina, and the resulting incontinence of fæces of the most revolting kind, together with the distress from the passage of the motions over the ulcerated surfaces of the cancer, fully justified the hope that an artificial anus in the loin would give relief. In Case 2 excision was justified by the malignancy of the growth, the suffering it gave rise to at each motion, and, besides, by its limitation and accessibility. In Cases 3 and 4 the growth was very chronic and bulky, and was causing obstruction alternating with profuse and most painful diarrhœa. Ulceration of the bowel above the stricture and perforation were therefore to be feared, if a free exit for the motions above were not immediately provided; this would also spare the cancerous surface the contact and straining of the frequent motions. Cases 5 and 6 were operated on almost entirely on account of severe pain, with diarrhœa, other troubles being less prominent. Morphia produced constipation, which aggravated the distress with each motion of the bowels. Finally, it was hoped that relief of the new growths from the irritation of defecation might retard their advance. In Case 7 the condition does not produce enough suffering to justify operation yet. In Cases 8, too, there is but little distress as yet, and as the patient can command the best private advice and any diet, the fæces can be kept in a condition to pass readily through the narrowed bowel, so that the patient, even at seventy-seven years of age, enjoys very good health still.

Operation.—In five cases colotomy in the left flank was performed by Amussat's incision, in one excision. The wounds were in every case guarded against septic contamination during operation by frequent sponging with carbolic solution, especially after opening the gut. The subsequent dressing consisted of carbolic oil on lint, covered with a pad of salicylated wool. All the colotomy wounds healed rapidly, almost completely by first intention, except in one case, where, as the healing was rather too rapid, I broke down some of the fresh union to allow of a little wider opening to the gut. Inflation of the latter from the rectum was practiced in every case, and the finding of the bowel was thereby much facilitated. In only one instance was the peritoneum wounded (Case 6).

But not one bad symptom followed, the wound being kept aseptic, as indicated, and the opening of the bowel having been deferred until the fifth day after the latter had been stitched by its muscular coat only to the skin. Stout silk cleansed in carbolic solution was used for the four primary stitches of the bowel, supplemented by a few finer threads between. Those cases, especially the last two, did best in which the mucous membrane was most carefully sewn to the cut surface of the skin. Without antiseptic precautions this would be undesirable, as tending to confine any pus formed in the deeper parts of the wound.

The eight cases briefly noted are as follows:—

CASE 1.—Mrs. C—, aged forty-five, was admitted into University College Hospital in April, 1880, and passed into my hands through the kindness of my colleague, Mr. Heath. Her previous and family history were very good, but one sister died of phthisis. "Bearing-down" pains were first noticed twelve months ago; then diagnosed elsewhere as due to "piles." Two months later cancer was found in the rectum here. Three months ago feces first passed per vaginam. Severe pain from the first as of labour. Patient is much emaciated and anæmic, and has phthisical consolidation of right apex; suffering acute. A hard mass of cancer involves the whole circumference of the rectum as far as can be reached with the finger, and even presents at the anus. It is most extensive anteriorly, where it has opened up the vagina and feces pass freely. There are great abdominal pain and rigidity of recti muscles. On April 21st I performed colotomy in the usual way, much helped by inflation of the bowel. Only one vessel required twisting. The wound was treated and dressed as described above. On the 28th the patient is noted as improved in every way; stitches removed (one on 26th) and a little pus pressed out of the posterior angle of the wound; feces commencing to pass by latter. From this onwards there was a steady improvement, only a little feces passing per vaginam; appetite, pulse, and strength much better, but phthisical state as before. Sometimes the pain in the rectum came on as before operation, but not as a rule. On May 24th the colotomy wound having healed and looking well, the patient left the hospital, still, however, very feeble.

CASE 2.—*Operation by Partial Excision.*

CASE 3.—W. N—, aged sixty-seven, admitted under my care July 28th, 1882. When first seen by me in February, 1881, he only complained of loss of blood with his motions for some months past. He had little or no pain, no constipation, and his health did not suffer. His family history was very good, and distinctly negated cancerous taint. There was at this time a mass of cancer in the rectum, about two inches and a half from the anus, and all round the bowel; it was lumpy and irregular, but did not appear much indurated; columnar epithelioma was diagnosed. Under the prolonged use of Chian turpentine pills the bleeding appeared to decrease, and he professed himself more comfortable. He remained thus until eight weeks before admission, when severe diarrhoea and pain in the fundament began; motions fifteen to eighteen per diem. The growth was now felt to be greatly enlarged, and to encroach upon the anus, though still not much ulcerated apparently; no glandular infiltration or generalization. He was much blanched and worn out by suffering (though naturally a very hale man) and was anxious for operation. This I performed on August 2nd, 1882, as described above, with every precaution against sepsis except the spray, both during and after and in the dressings already described. The wound healed almost entirely by first inten-

tion, and the patient looked and felt extremely well throughout. The motions passed by the new anus on and after the third day. The stitches were removed on the sixth day, and he was out of bed on the sixteenth, leaving for the Convalescent Home soon after, the artificial anus working regularly. Some slight mucous discharge still came away per anum.

CASE 4.—W. H—, aged sixty-nine, admitted under my care July 27th, 1882. He has a large and healthy family and good family history, which distinctly negatives cancerous taint; he is healthy but of very nervous temperament, and suffers from "winter cough." Eighteen months ago melæna and diarrhoea, alternating with constipation, were first noticed; much aggravated for the last three weeks, and accompanied by distension of belly and narrowed motions, but no blood now; suffering, emaciation, and weakness now much marked; no glandular or other generalization. "In the rectum is a firm broad mass, encircling the bowel and attached to the sacrum, its position not being altered by straining. It gives all the characters of columnar epithelioma. The patient's condition being very miserable, I performed colotomy also on August 2nd, 1882, precisely as in the last case, having only to search a little deeper for the gut in the subperitoneal fat. On the sixth day the wound was almost perfectly healed by first intention, but as the opening appeared a little small, I broke down some of the fresh union for about an inch forwards. This of course retarded definitive healing, and was followed by considerable suppuration. On the seventh day it was noticed that the pulse was very peculiar; it was 140 to 170 usually, but at one time reached 196. It was counted several times daily by many observers, and was generally the same; in sleep it was about 120. Some sphygmographic tracings are preserved in the hospital register. I was unable to account for this condition as long as it lasted, as the patient seemed and felt remarkably well and in good spirits. His temperature was below 100° for almost the whole week during which this rapid pulse was noticed. Abundant stimulation and bromide of potassium produced no change. The enlargement of the wound had the desired effect, the feces from this time onwards passing almost entirely from the side, except when violently purged, when some made its way into the rectum. With the exception of oedema of the left leg, attributable, I think, to debility, there is nothing further to note, except that the patient improved steadily, and left the hospital for his own home at the end of September, the new anus working satisfactorily.

CASE 5.—R. M—, aged thirty-four, admitted under my care on July 28th, 1882. He had been a very strong man, but when first seen, five weeks before admission, he had an expression of much suffering, standing with his back bowed down and his hands resting on his knees, the latter slightly flexed, complaining of intense gnawing pain down his legs as low as the ankles. His face was pale and haggard from want of sleep for a long time. His family history was good, both parents being alive and aged seventy-two, and hereditary cancer distinctively negated. About five months before melæna and pain on defecation were noticed; his motions, which often reached twenty a day, consisting of almost pure blood at times. When first seen before admission, I found a new growth encircling the bowel just within reach of the finger, its upper margin being only accessible during anaesthesia; it appeared about an inch deep, was rugged, ulcerated, bled slightly, and was extremely painful to the touch. The mass seemed generally movable, but much less so behind, where it ap-

peared more or less fixed to the sacrum. Other efforts to give relief having failed, the patient became anxious for any operation which would afford him relief from his intolerable suffering. As he was young, generally healthy, and the growth had only appeared comparatively recently, and was still limited, I hoped to be able to excise it completely as in Case 2.¹ But there was some doubt in my mind whether it could be reached as easily, and also whether it was not to some extent extending towards the sacrum, and fixed there. I determined then to attempt excision, at all events as far as the preliminary incision in the middle line of the anus to the coccyx, and if the growth could be reached remove it. This was done on Aug. 10th, and in the wide opening secured by the first incision, it was found that the growth was too much fixed behind, and could therefore be drawn so little within reach that it would not be safe to go farther. No serious trouble followed this exploration, and on Aug. 23rd I performed colotomy precisely as in the other cases, except that more care was taken to unite the mucous membrane all round the skin wound with extra stitches of fine silk, in order to secure more complete union by first intention. All went well from this onwards. On the fifth day the stitches were removed, three from the skin and seven from the mucous membrane. The whole wound, except about a quarter of an inch at the posterior angle next the colon, healed by first intention. On and after the sixth day motions passed by the new anus. With the exception of a little diarrhoea there is nothing to note until the patient left for the Convalescent Home, except that a little faeces still passed occasionally per anum. He was greatly relieved by the operation, and looked well.

CASE 6.—Mrs. J.—, aged sixty-two, admitted under my care August 17th, 1882, a fairly healthy woman, with a good family history distinctly negating hereditary cancerous taint. About two years ago melæna and frequent action of the bowels were first noticed, but there was no pain or discomfort. One year ago she began to suffer from "aching" pain in the rectum. The bowels were moved at that time at least eight times a day, and never without blood. For the last six months the discomfort has much increased, especially after each motion, but also on sitting down, when the pain is most severe both at the anus and down the thighs. In the rectum there is now a large mass of new growth round the gut, about two inches from the anus, extending beyond the reach of the finger; it is nodular and only slightly ulcerated. The vagina is only separated from the mass by a very thin layer of healthy tissue. On August 23rd I performed colotomy as in the last case. On passing the needles through the colon, and making a cautious cut between the stitches for about half an inch I found that one of the latter had wounded the peritoneum and allowed the inflated air to pass into the abdomen, and also that my incision in the wall of the bowel had wounded the peritoneum without opening the latter. I therefore sponged the stitches and wound afresh with carbolic solution and united the peritoneal edges with a fine continuous carbolized silk suture. Then drawing out the first stitches I passed fresh ones across the wall of the gut, but this time only through its muscular coat so as not to enter the bowel. These were now secured to the skin, and the operation wound was united in the usual way. Everything was thus left until the sixth day without opening the gut. By this time the peritoneal surfaces were soundly united; the rest of the operation wound

had healed by first intention without a drop of pus, and I found the muscular wall of the gut glued firmly in the opening by semi-solid lymph. The gut was now opened with a scalpel and the mucous membrane stitched to the skin in the usual way. Nothing could have been more satisfactory than the whole course of this convalescence in spite of the wound of the peritoneum. There was not a bad symptom and no suppuration, and I regard it as the best of the series. From the seventh day onward the new anus acted well, a trace of faeces passing occasionally per anum still. Before the patient left for the Convalescent Home a bougie was passed into the wound a few times, as it inclined to shrink.

CASES 7 and 8.—Of these I need say little in addition to the general notes of the group given above. They were males aged sixty-eight and seventy-seven respectively, and their condition so far should not justify the performance of colotomy. The last, a private case, I still hear about frequently.

A few notes as to the subsequent history of the cases operated on will serve to complete the series up to date. Case 1 I cannot trace after her discharge from the hospital. Case 2 was alive and in excellent health when I last saw him, sixteen months after the operation, without a trace of recurrence. Case 3 began to improve at once after operation, and on his return from Eastbourne looked strong and healthy. He has since had occasional trouble in regulating his bowels, as he is inclined to constipation. The flank opening is inclined to shrink, and I have been obliged twice to dilate after incision of the edge, the last occasion being about a week ago, or just six months after operation. This was necessary, as without a very free lumbar opening in his case some of the faeces tended to work into the rectum, and set up the old pain. The patient had, however, been able to return to his work as College porter before this, and got about without great discomfort for a time, until this shrinking, combined with constipation from other causes, gave rise to trouble. I have no doubt that this difficulty will shortly be overcome.² Case 4 was much relieved by operation. He returned for examination from time to time and professed himself greatly improved, and he had manifestly grown stronger and gained flesh as he got about out of doors. In this instance there was a tendency to prolapse of the colon for a couple of inches, but it was easily kept up by Mr. Bryant's rubber-pad, modified slightly by the author to meet this particular case. When last seen by the writer in December he had the appearance of a fairly healthy old man, and was able to get about in the fresh air without discomfort. Within the last few days I have learned from his son that just before Christmas last he had a severe attack of his usual "winter cough," and died on Dec. 26th, 1882. The diagnosis made by his medical attendant as to the cause of death was "primary bronchitis." I regret that as I was out of town at Christmas an autopsy was not obtained, which would have shown the state of the bowel and the new growth. Case 5 suffered much and almost constant pain in the rectum after the first couple of months, though his general health and appearance were much improved. It seemed from the first as though in this case some of the lumbar nerves might be implicated in this growth from the character of the pain. Later, although the new anus acted most satisfactorily according to his own account, and the rubber plug and pad saved him from any unpleasantness during the day, still the

¹ Vide Brit. Med. Journ., Jan. 6th, 1883.

² Since writing the above all his trouble from constipation, etc., has been relieved by the last dilatation, and he is now comfortable.

old pain in the back and thighs came on again and again with much severity, and required morphia. But, as contrasted with his state beforehand, he was much improved for some months by operation. But before leaving town for a short time at Christmas I went to see him at his home and found that generalization of the new growth had plainly commenced. He had a nodule as big as a pigeon's egg in the middle of his forehead, and probably deposits in his lungs. When I last saw him, a month ago, the frontal nodule was much enlarged, and his liver was enormously increased in size also. He had then marked cancerous marasmus, and died two days later (Jan. 29th). The colotomy wound had acted well up to the end. Case 6 is, perhaps, the best result of the five colotomies. For four months after operation she had only a trace of dull pain in the rectum on sitting down. Her bowels acted, she stated, regularly through the loin once or twice a day, and in the intervals the side remained quite clean and comfortable. Every time she called at the hospital it was thus. She was cheerful and contented, and said she had gained flesh; and, indeed, she looked remarkably well, and not in the least troubled by the lumbar opening. Within the last week or so she has again come up to be examined, and she tells me that quite lately the gnawing pain in the rectum has increased much, and has called for the use of morphia. The consequent constipation has caused some difficulty in evacuation by the lumbar opening, which is of moderate size, and some motions have therefore found their way into the rectum. This, I have no doubt, will be easily rectified. In the meantime she goes about with no discomfort from her side, and looks still fairly well. Cases 7 and 8 have not been seen lately; but of the latter I have learned that he has commenced to pass blood from the rectum in considerable quantity. All of the last four colotomy cases wore Mr. Bryant's rubber plug and pad for a time. In Cases 3 and 5 it acted well when modified; in Cases 2 and 6 it was discarded after a time although altered many times to make it fit.

This group of cases appears to me to offer data for help in the selection of cases for operation, and then for the choice of the particular method of operation. Only one out of eight, it will be seen, was suitable for excision, and only five for colotomy. It will be noted that all the operations were followed by relief, the excision by permanent cure, it may now be hoped. Case 1 I could not trace. Case 2 was alive and well, with no recurrence, sixteen months after excision. Case 3 is alive and in very good general health still, six months after colotomy. Case 4 lived for five months after operation in fair health and able to go about, and then died of bronchitis. Case 5 was relieved of much suffering for at least two or three months, and his general health was very much improved until generalization set in. He lived over five months after operation. Case 6 is still alive and well, nearly six months after the lumbar anus was made. She goes about still without discomfort from the latter, and though she is now beginning again to have pain in the growth in the rectum, her condition generally is good.

I cannot help thinking that, though there are undoubtedly many cases of cancer of the rectum for which colotomy is not called for at any time, still there are many cases in which it would give great relief in which it is too long deferred, and its full benefits are therefore not enjoyed by the patient. Finally, there must be many cases suitable for excision if placed in our hands *early enough*.

Harley-street, W.

THE BLUE-GUM STEAM TREATMENT OF INFECTIOUS DISEASES.¹

By J. MURRAY GIBBES, M.B., C.M., etc.,

Coroner, New Plymouth, N.Z.

My object in this paper is, first, to bring forward a treatment of diphtheria I have found very successful; and, secondly, to suggest that a similar treatment might possibly prove equally successful in other infectious diseases. The treatment is that of keeping the patient in an atmosphere of blue-gum (*Eucalyptus globulus*) steam. It is an acknowledged fact that in blue-gum we have a most perfect disinfectant; not an artificial one, but one of nature's own; one always at hand, for it will grow in temperate climates. The green leaves hung in a bedroom keep it sweet; leaves placed on a wound, steam inhaled from it, or its infusion drank, or injected into wounds, all answer equally well. Professor Lister speaks highly of the eucalyptus oil for wounds, and it is also spoken highly of in rheumatism. It has not an unpleasant smell, and is tolerated by nearly all. By infectious diseases, I mean those which are caused by micro-organisms. I think it is an established fact that typhoid fever, measles, small-pox, whooping cough, tuberculosis, scarlatina, etc., are caused by fungoid growths. We know that they are introduced into the body by means of dust floating in the air, by milk, water, and food of all descriptions. After they have obtained entrance into the system, they multiply until they produce their specific effects. They pass out of the body in myriads, by means of the breath, perspiration, and discharges. Infection means the air being poisoned by these germs, and the incubation of a disease is the time required for their propagation into sufficient numbers to interfere with health, and that time seems to be lengthened or shortened according to the quantity introduced, the peculiarity of the different germs, or the state of the system at the time. That a specific germ can alone produce a specific disease is an established maxim. It having been proved that certain germs produce certain diseases, the question arises, How can they be destroyed? Not only how we can cure the disease, but how can we prevent it spreading? Say, for instance, we have a case of scarlatina in a town which had been free from that disease. How can we prevent its spreading through the town? The answer, of course, would be isolation and disinfectants, and it would be perfectly correct, disinfectants having the power of destroying these germs. It is on this point I ask to draw attention—viz., the best and most effectual method of using disinfectants, so that the germs can be destroyed before they can do mischief. I stated that the breath, perspiration, and discharges coming from a patient suffering from an infectious disease are laden with germs all ready to do mischief. At the present time disinfectant lotions, gargles, sprays, and internal remedies are used, and disinfectants poured on the various discharges; so far, so good, but the breath is laden with disease, and the evaporation of the perspiration also assists in poisoning the atmosphere of the room. Ventilation is then carried out to purify the room, but what becomes of the germs? They are dispersed into the external atmosphere to carry disease to others in all directions, and here we come to the root of the matter. If we wish to stay epidemics from spreading, not only must we disinfect the discharges, but we must destroy every germ which comes from the body, either by the breath or

¹ Read before the Taranaki Medical Association, October 4th, 1882.

otherwise, and to do this effectually we must keep the patient in a disinfected atmosphere. This must be done in every disease which is caused by micro-organisms, and until it is done we shall never be able to stay epidemics. It is the only true scientific method of dealing with disease. How is this best to be done? The discoveries made during the last few years and months revealed to me the cause of our many failures in curing these diseases, and the unscientific methods generally recommended. We gave remedies without having any idea how or why they cured disease; but now science has made vast strides and a great deal that was before obscure is being made plain; we have arrived at the root of the matter, and although perhaps, we do not as yet know how they cause disease, yet we have a solid foundation to start from. Professor Lister revolutionized the treatment of wounds when he brought forward his grand treatment of operating in a disinfected atmosphere. "The germs cause disease, therefore keep them away" he said, and the world bowed before his dictum feeling that he had hit the right nail on the head. If this answers in wounds, why should it not answer in infectious diseases?

After perusing the papers read before the International Congress, 1881, I felt convinced that the only efficient treatment of infectious diseases was to keep the patient in a disinfected atmosphere for several days, and I had an opportunity of trying my treatment sooner than I expected, for in October of the same year an epidemic of diphtheria broke out in a township sixteen miles from here (New Plymouth, Taranaki).² I had made for some years experiments with *Eucalyptus globulus* in various diseases with most satisfactory results—namely, in leucorrhoea and other discharges, gonorrhoea, and so-called laryngeal phthisis, croup, bronchitis, etc. My experience with disinfected steam has only been in the above epidemic, and the results have been most encouraging. Thirty-seven cases in which the treatment was carried out recovered without a bad symptom, such as paralysis, without any medicine except castor-oil, and without stimulants, which disproves the statement that diphtheria requires a large quantity of alcohol. The disinfectant I used was made by pouring boiling water on blue-gum leaves. The patients were kept in the moist atmosphere for some days. I mopped the throat with dilute solution of perchloride of iron and glycerine every eight hours, and then covered the pharynx with powdered sulphur. This I did in most cases, but the others recovered equally well. Two young ladies, aged seventeen and nineteen, coughed up complete casts of the large bronchi. An old lady, after I had mopped her throat once, refused to have it done; she had a very dense patch behind and on the right tonsil, the glands of her neck were very swollen and tender, the neck enlarged, and the breath was most offensive. On the third day half of the membrane had come away in small pieces, like grains of rice, the breath was sweet, and the swelling of the neck had nearly disappeared, and she made a perfect recovery. The epidemic was an unusually severe one, judged by the number of deaths of those who were treated by other means. The last cases which occurred took place in two families closely allied, five children and their nurse being attacked. I attended two of the children (the first and last attacked) and the nurse. They recovered, whilst the other three, who were attended by a colleague, died. Local remedies are very good, but they are only a part of the treatment. We cannot perpetually keep spray applied to the throat,

the children moving about from side to side of the bed. We must take the cure to them, and we can only do this by means of steam. My mode of procedure is very simple. I pour boiling water on blue-gum leaves, in a tub, jug, or chamber, which I place beside the bed, and change it every half hour. If only one child is ill in the room I improvise a tent over the bed, either by means of an open umbrella with a sheet above it, or by placing a sheet over the sides or ends of the bed, and enclose the patient. It is wonderful to see how soon the pain in the throat and the swelling disappear, and the fever also. Pain in the stomach is the first symptom most patients suffering from the malady experience, even before the throat is affected. At first I used a simple fever mixture; but I found it was not needed, as the skin acted more or less according to the amount of steam used. The patients were able to eat bread-and-butter, the throat not being sore because I had not burnt it, as is the barbarous treatment recommended by some. In diphtheria the throat is never very sore unless caustics are applied. In simple cases of it many remedies will answer; but if it once gets to the larynx and below it no remedy can touch it except steam. The laryngoscope showed patches on the vocal cords, and the breathing that it had extended lower; and in some cases where suffocation seemed imminent the distressing symptoms would be suddenly relieved by the membrane being coughed up. One young lady remarked, "The steam saved my life."

Although blue-gum steam has answered so well with me, it is not the remedy alone that I wish to bring before the profession, but the principle of the treatment, feeling sure that when a thorough trial has been given to it no other treatment would be found to give such satisfactory results; and if it answers in diphtheria it would answer equally well in other infectious diseases. In typhoid fever the heat would be lessened, the skin kept moist, and the bowels would not have to do double duty. In pertussis it would allay the irritation of the bronchial mucous membrane in the same way that it does in bronchitis, croup, and asthma. In scarlatina the congestion of the pharynx and the skin would be relieved. In so-called laryngeal phthisis it has given most satisfactory results. In influenza the infusion of *Eucalyptus globulus* is a very popular remedy, and it is one of the most infectious diseases. If blue-gum steam were adopted as a disinfectant, or any other drug, in the ward of a hospital, I should have a boiler outside, with pipes leading into the ward along the floor, with small holes in them to allow the steam to pass through, and have a stopcock at the commencement to regulate the amount of steam. A pipe could also be placed along the wall, with mouth-pieces attached, for those patients who suffered from throat affections. The boiler could be placed in a sand bath, so as to regulate the heat of the water, or a gas stove used. The leaves could be placed in a net in the water, and changed as often as required. The advantages of the blue-gum steam treatment are that it can be used by ordinary attendants; in fact, a farmer at Tikorangi treated seven cases and cured them. In one of these cases, he informed me, the membrane returned again and again for three weeks. He trusted entirely to the blue-gum steam. No internal remedies are required.

LATERAL CURVATURE OF THE SPINE.¹

By E. NOBLE SMITH, F.R.C.S. Ed.,

Senior Surgeon and Surgeon to the Orthopædic Department of the Farringdon Dispensary.

THE following paper contains a short account of the nature, causes, and treatment of lateral curvature of the spine. From the great variety of views which have been expressed upon this subject I have selected those which have seemed to me from observation and from practical experience to be most worthy of acceptance. I believe that the views which I have adopted cannot be considered in any sense extreme, and that the plan of treatment which I shall describe is based upon sound surgical principles, and is free from the objections which have been justly raised against many other methods.

In lateral curvature of the spine there are usually two curves, because when one is produced from some special cause in one direction; another, as a rule, forms in the opposite direction to allow the equilibrium of the body to be maintained. The manner of formation of the secondary or compensatory curve is shown in the following diagrams, which represent a case in which obliquity of the pelvis acts as the cause of the primary curve.

Fig. 1 shows the position of the spine when the pelvis is oblique. Fig. 2 indicates the position the spine would assume (if the lumbar curve remained fixed) when the pelvis was restored to a horizontal position. Fig. 3 shows a compensatory

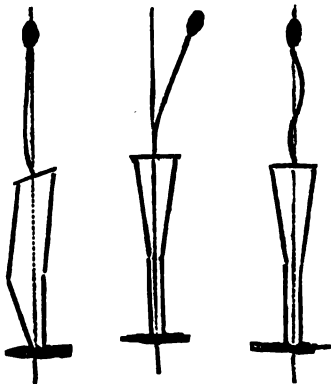

Fig. 1.

Fig. 2.

Fig. 3.

dorsal curve formed by the efforts of the patient to maintain the equilibrium of the body. The changes represented by Figs. 2 and 3 necessarily take place very gradually and almost simultaneously. Several alternate curves may thus be produced, but the primary curve may be either lumbar, dorsal, or cervical, according to the cause. Obliquity of the pelvis produces a lumbar curve first, wry-neck will give rise to cervical curve, and frequent obliquity of the shoulders will cause the primary curve to appear in the dorsal region.

The most remarkable feature of the deformity under consideration is the rotation of those vertebrae which are involved in the curves. The vertebrae rotate upon their vertical axes, so that their bodies turn in the direction of the convexity of the curve and their spinous processes in the direction of the concavity. This very important part of the deformity is shown in Fig. 4. It is probable that this twisting of the vertebrae is due to the fact

that the posterior portion of the spine is a part of the parietes, and is thus to a great extent confined to the median line; whereas the bodies of the vertebrae project into the cavities of the chest and abdomen, and are free to move to the right and left. Dr. Judson, of New York, has illustrated this theory by a mechanically arranged spinal column. In some cases the apices of the spinous processes are found removed but slightly from their central vertical normal position, while the anterior surfaces of the bodies of the vertebrae form a considerable curve. The diagram (Fig. 5) represents such a case, the black central line indicating the position of the spinous processes, and the dotted line indicating the extent to which the bodies of the vertebrae project laterally. The appearance of this rotation is therefore deceptive if we judge of the curves entirely by the position of the apices of the spinous processes. The nature of the case has occasionally even been mistaken, because the spinous processes have been nearly in a straight line, while the protruding ribs have been taken for some morbid growth. I lately had such a case in which the mistake had been made under my care. But as a rule the symptoms are less obscure, the deformity being well marked. The whole trunk is rotated, and the protrusion of the ribs in the dorsal region and the transverse processes in the lumbar are characteristic features, these projections occurring in proportion to the amount of twisting of the vertebrae. The scapula upon the side of the convexity is pushed backwards by the ribs and upon the opposite side the scapula drops with the shoulder, and other alterations occur of which I need not now speak.

Some of the chief alterations of form produced by rotation are well shown in the diagram (Fig. 6), which represents a supposed transverse section of the thorax about its middle. The dorsal curve is to the right, consequently the ribs upon the right side project backwards and the left breast forwards. The space for the right lung is much compressed. As the deformity increases (and its tendency naturally is to increase), pressure upon the nerves and viscera occurs to a serious extent, and the bodily health of the patient suffers. Functions become disturbed, and pain may occur in various localities. It does not seem to me a matter for surprise that a great variety of symptoms may thus be produced. In the early part of last year I had a case in which the symptoms were of such a character. A gentleman with severe lateral curvature was sent to me who had been incapacitated for work by severe functional disorders of the liver and stomach and by persistent sciatica. These complaints might, of course, have arisen independently of the curvature, but as they resisted all ordinary treatment for several months, and rapidly disappeared when the curved spine was supported mechanically, I presumed that they were caused by the deformity in the manner which I have alluded to.

Causes of Lateral Curvature.—These may be divided into *predisposing* and *exciting* causes. The exciting causes may give rise to the affection when the predisposing causes do not exist, and the predisposing, if severe, will allow the formation of curvature although the exciting causes are so slight that they are scarcely if at all distinguishable, or possibly do not occur. The *predisposing* causes are probably all circumstances which give rise to debility. This debility may act generally, or it may affect the dorsal muscles, and disenable them to retain the spine in an upright position for long periods. The condition of the bones may predispose to the formation of curves. In rickets, the vertebrae, if affected, readily give way to lateral pressure. In general debility, and especially

¹ A paper read before the Harveian Society, January 4th, 1883.

when the scrofulous diathesis is present, the bones are more readily influenced than they are in health. If a child grows rapidly curves are sooner formed than when growth is slow. With regard to the general health, I may add that all habits and circumstances which depress the bodily health may act as predisposing causes, and especially those in which the muscles of the back are overtaxed, or in which their development is retarded. We all know how much more frequently

growing spine; and a slight curve once commenced is very easily increased. Much standing, and the use of forms and straight-backed chairs, have a great influence in producing lateral curvature in this manner. We know how much the poor suffer from these influences; and lateral curvature of the spine occurs more frequently among the working classes than is generally stated. Among the rich the spines of young girls are equally or more severely overtaxed. With the object of making

Fig. 4.
After Bouvier.

girls suffer than boys from lateral curvature, and it is very common to find some retardation of sexual development or some derangement of the commencing menstruation. The natural delicacy of formation of girls may possibly be one reason for their greater liability to the affection; but their sedentary occupations obliging them to try to rest their backs, by allowing the spine to subside laterally, is probably a more potent cause. If the back is not rested directly the muscles become tired, the spine subsides to one or other side, and is supported in that position chiefly by the articular processes. The frequent pressure in one direction (for the subsidence generally takes place repeatedly upon the same side) soon causes inequality of growth and alters the position of the soft

girls "refined in their manners," an unnatural restraint is placed upon their movements, and they are not allowed to follow the dictates of nature, which would lead them to take a sufficient amount of exercise in an unconstrained manner to ensure the maintenance of their health and form. Children require recreation, not merely exercise. Young people are not benefited by long stately walks; they require freedom, ease, and play; and when they are deprived of such occupation, the health always suffers and the spine frequently becomes deformed.

Exciting causes.—Conditions which disturb mechanically the equilibrium of the spinal column continuously or for long periods act as exciting causes. The chief of these I will now enumerate.

ate:—1. Inequality in length of the lower extremities, causing obliquity of the pelvis. 2. Inequality of weight of the two sides of the body, as, for instance, when an arm has been lost. 3. Disease or injury, producing contraction of one side of the thorax or abdomen. 4. Alteration in the position of the head—wryneck, for instance. 5. Bad habits of position, sometimes the result of the predisposing causes.

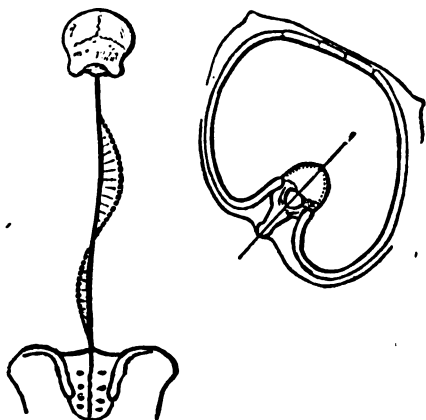

Fig. 5. After A. Shaw in "Holmes's System of Surgery." Fig. 6.

The following are some of these bad habits of position—1. Standing frequently upon one leg, 2. Bending the body for writing, etc., at a low table. 3. Bad positions at other work. 4. Carrying heavy weights always upon one side. 5. Standing at school or sitting upon stools or forms without backs, or with unsuitable backs.

1. *Stimulating Liniments* used to the back are applicable in the majority of cases when there is loss of muscular tone.

2. *Rest*.—When no instrument is used the patient should rest in a chair which fits into the natural lumbar curve of the back, or in the prone position upon a couch. The latter plan prevents the subsidence of the spine and the formation of round shoulders, and tends to bring the dorsal muscles into play beneficially.

3. *Mechanical extension and pressure*.—I will not attempt to describe the various machines which have been devised for extending the spine and at the same time forcing in the curves. The result of such treatment has seldom if ever been satisfactory, and some of the apparatus which have been used may justly be called barbarous.

4. *Muscular exercises* are employed for two purposes: (1) To strengthen weak muscles; (2) to act directly upon the curves. The former, which are highly beneficial in suitable cases, I need not describe, but the latter demand further attention.

The exercises which have hitherto been recommended for acting directly upon the curves have been devised with the object of drawing out the concave side of the curve, by employing the arm of that side, the patient exercising upon a trapeze with that arm higher than the other. Now, the muscles which extend from the arm to the spine in the concavity of a dorsal curve are the trapezius, the rhomboidei, and the upper part of the latissimus dorsi, and these are attached to the spinous processes of the vertebræ. We have already seen that the spinous processes are directed, in consequence of rotation of the vertebræ, towards the side of the concavity, and that the rotation is the most important part of the distortion, and the part which may produce the chief amount of deformity. The effect of this exercise is obviously to draw the spinous processes further in the direction of the concavity, and consequently increase the rotation of the vertebræ. The arrow proceeding from the

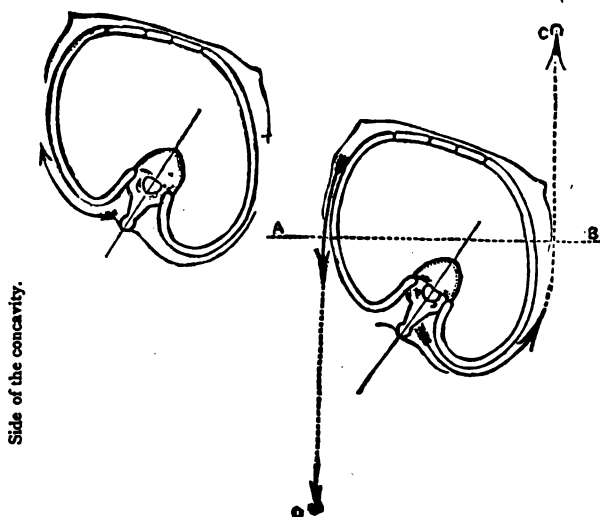

Fig. 7.

Fig. 8.

Treatment.—In the first place the causes must be removed if possible. A short leg, for instance, must be raised to its proper height. The general health must be treated, and this is a very important matter. The special means of treatment to be considered are—1. Local stimulants. 2. Rest. 3. Mechanical extension and pressure. 4. Muscular exercises. 5. Mechanical support and pressure.

spinous process in Fig. 7 will show the direction in which the muscles already referred to will act, for it must be observed that although both arms are to be used in the exercise, yet the muscles which attach the arm to the spine upon the side of the concavity are brought into greater action than are the same muscles upon the opposite side. The position of the body necessitated by this ex-

ercise would be a good one if it were not brought about by the action of the muscles enumerated above.

The plan of special exercises which I have devised for cases in which there is much rotation consists in the use, upon the convex side of the curve, of the muscles above referred to, with the object of drawing the vertebræ round towards their proper position; and upon the concave side of the curve the patient has to exercise the muscles which extend from the arm to the front of the body, with the object of drawing backwards that prominent side of the thorax. The arrows in Fig. 8 showed the direction of the force used. A weight is raised towards the pulley, c, by the patient drawing a cord towards the body with the right hand (presuming there is a dorsal curve to the right), and the left arm is worked in the opposite direction, as indicated in the figure. The pelvis must be fixed in a suitable chair during these exercises. Although this plan of exercise acts directly only upon the dorsal curve, yet the resistance of the pelvis to the action of the arms tends to twist the lumbar part of the spine in the opposite direction, and thus produces the exact action that is wanted. If more direct action is required for a lumbar curve, the quadratus lumborum may be brought into use upon the convex side of the curve. The rationale of this system is to shorten the curves upon their convexities and to rotate the vertebræ back to their normal position. Slight variations in these exercises must be made to suit the peculiarities of individual cases, and general exercise of the erector spinæ muscles of both sides should always be carried out in addition to the special exercises now described.

5. *Mechanical support and pressure.*—If improvement does not soon take place as a result of the plan of treatment already described, recourse should be had to some mechanical appliance, which, however, should be as light and simple as possible, and which should *not interfere with due use of the muscles* during ordinary occupations. The mechanical instrument should always be adapted by the surgeon himself. Moreover, the construction of so important an apparatus ought not to be left entirely to the instrument maker; the special knowledge of a medical man is required to fully understand the nature of the deformity, and to properly determine the places where and the manner in which any pressure or support is necessary or justifiable.

I have elsewhere described fully the necessary mechanical treatment of these cases, but I may observe here that the spinal instrument should *not* interfere with the use of the muscles of the back, but should act chiefly as a support ready to rest the spine in an upright position directly the muscles are unable, from fatigue, to keep the column upright. By such means the spine is prevented from subsiding into a position of lateral curvature, and time is gained during which the muscles may be strengthened, and the general health of the patient improved. If the instrument is constructed upon these principles none of the objections which have been so often justly raised against mechanical treatment can be applied to it, and we shall be enabled by its help to treat our patients much more effectually and rapidly than if we depended upon non-mechanical treatment by itself.

Queen Anne-street, W.

—THE English Committee of the Darwin Memorial Fund, which has its head-quarters at the Royal Society, London, has now received (inclusive of subscriptions from abroad) £4,000.

REMARKS ON THE RELATION OF THE TUBERCLE BACILLUS TO PHTHISIS.¹

By C. THEODORE WILLIAMS, M.D., F.R.C.P.,

Physician to the Hospital for Consumption, Brompton.

SINCE the announcement of Koch's celebrated discovery of the tubercle bacillus, attention has been closely directed to its detection in the sputum of phthisis, and subsequent observations have confirmed its intimate connection with the disease, though the exact part it plays in its pathology and causation will require much further research to elucidate. The first question of importance which meets us is, Are the bacilli always present in the sputum of phthisis, and absent in that of other diseases? Important evidence has been given on these points by Drs. Balmer and Fraenkel, D'Espine, and Drs. Heron, Whipham, and Dreschfeld, and now I propose to give the results of the examinations which have been carried on in the Brompton Hospital for some months with a view to test Koch's conclusions. The number of patients whose sputum has been tried is one hundred and thirty. Some earlier examinations were made, but as they were few in number, and not systematically carried out, I have omitted them. The method used was that of Dr. Heneage Gibbs, the staining being accomplished by his magenta aniline solution and chrysoidin; in some later slides methylene blue was substituted for the chrysoidin. The specimens tested were either taken from the sputum collected during the twenty-four hours or from that expectorated in the early morning, and the rule adopted has been in the case of a negative result to repeat the examinations two, three, or four times so as to ensure accuracy. Forty-five of the patients were under my care, and eighty-five under the care of my colleagues, Drs. Douglas Powell, Tetham, Reginald Thompson, and Roberts, who kindly allowed me to make use of the examinations and records made in their wards. In one hundred and three cases the slides were prepared and examined by my clinical assistant, Mr. G. Perez, and in twenty-seven by my other clinical assistant, Mr. Waugh. Dr. Powell's thirty cases have been carefully checked by him, and I have myself gone through all the others with a good Zeiss microscope with an F objective and a No. 4 eyepiece, giving a magnifying power of 1020. Twenty-one patients were examples of various lung affections other than phthisis; two were cases of asthma, five of emphysema, two of bronchitis and emphysema, three of bronchitis, one of pleurisy, three of bronchiectasis, one of pneumonia, one of empyema, two of pulmonary congestion (the result of heart disease), and one was an obscure case of lung induration. In no one of these did the sputum contain bacilli. The one hundred and nine phthisical cases consisted of acute and chronic forms, and included instances of tuberculo-pneumonic phthisis, of scrofulous pneumonia, of fibroid, catarrhal phthisis, and a large number of cases of chronic tubercular phthisis. Cavities were detected in one or both lungs in eighty-one of these patients, nine were in the stage of early consolidation, the rest were undergoing softening or were cases of old tubercular induration with emphysema and fibrosis. In the 109 phthisical cases we detected bacilli in 106—that is, in all but three; and even of these three, in one it could not be affirmed with certainty that they were absent. There was a difference of opinion between the two observers, and unfor-

¹ Made at the meeting of the Medical Society of London, Feb. 12th, 1883.

tunately the patient left the hospital before we obtained a further specimen. In another, a case of contracted cavity, under my charge, the sputum was so scanty that it was very difficult to obtain any, and I have my suspicions that the secretion, owing to the blocking of the cavity bronchus, was entirely bronchial. In the other case the slides were not very successfully mounted and circumstances prevented our obtaining more sputum, but I thought it just to include it in the list.

So far our results agree with those of previous observers as regards the specific character of the bacilli, and the fact that none were found in the cases of bronchiectasis, in which the expectoration was extremely fetid and abundant, separates the tubercle bacillus from any of the numerous organisms connected with fermentation and decomposition.

Most of our consumptive patients had cavities, but it will be observed that nine were cases of early consolidation. These were all cases in which both the history and the physical signs forbade any suspicion of a cavity, and I offer them as a proof that the bacilli are found in connection with tubercle formation, and not only with softening and excavation. It will be remembered that in some of Koch's specimens they were seen together with miliary granulations. Dr. Heneage Gibbes' distinction of two kinds of tubercle, one containing bacilli and another devoid of it, is most important.

The second question seems to be as to the relation between the numbers of the bacilli and the progress of the disease. Is their abundance coincident with great activity, and does their disappearance indicate quiescence? In dealing with this point we must bear in mind the different expectorating powers of patients, some of whom, especially in the later stages, have great difficulty in ejecting the secretion, large accumulations of which are often found in cavities after death. Then, again, we must remember Dr. Gibbes' caution as to ensuring that the material comes from the lungs and not from the throat. A third consideration is, What do we understand by activity of disease? I take it as signifying either extending tuberculization or softening and excavation, or a combination of both processes. The occurrence or pyrexia, and specially of prolonged pyrexia, indicates some form of activity, though it is possible, as I have shown elsewhere, the disease can progress and extend without this concomitant. Where, however, it is present, we may be quite certain that active tuberculous processes are going on.

Temperature observations were carefully taken in all the 109 cases, and in 51 pyrexia, ranging from 100° to 105° F., was present at the time of the examinations. In some of these pyrexial cases the bacilli were very abundant, but in others, though the sputum was abundant, bacilli were few, and this in spite of numerous careful observations. In one patient under my care, a case of acute tuberculo-pneumonic phthisis, which terminated fatally in ten weeks, the temperature ranged from 100° to 103° F. Cavities formed in both lungs, and the expectoration was fairly abundant. Bacilli were present, but always in small numbers. In another case of somewhat acute disease, where a cavity existed in one lung and a second one was forming in the opposite lung, the temperature ranging from 99° to 103° F., it was only after four trials that any bacilli whatever were detected. In some chronic and quiescent cavity cases the bacilli have been found in fair number, and even abundantly. In two cases of hæmoptysis, under the care of Dr. Tatham, bacilli were detected in the blood expectorated. With regard to the proportion present

during periods of quiescence or arrest of the disease, I should regard their total disappearance as an eminently favorable sign. Out of four cases of contracting cavities where very favorable changes were progressing, bacilli were detected in three, but in small numbers; in the fourth case, above mentioned, none were found. Therefore we are hardly justified in concluding that there is any definite ratio between activity of disease and number of bacilli, though as a rule they are few in cases where the disease is quiescent.

Now, what bearing has the bacillus on the question of the contagion of phthisis? And to answer this question we must ascertain whether they exist in the air exhaled by consumptive patients, as well as in their sputum. Dr. Ransom has found them in the air of a room containing several advanced cases of phthisis, and they have also been detected in a respirator worn by a patient by Dr. Sharnley Smith. I have suspended glass plates covered with glycerine in the extracting flues of the Brompton Hospital, and thus subjected them to a stream of air with a velocity of 300 to 400 feet a minute issuing from numerous wards containing consumptive patients. In this way I sought to obtain a concentration of the exhalations, and on testing the plates they were found to contain abundant bacilli. Of course this was bringing the material to a focus, but still we may fairly conclude that the breath of one consumptive patient contains some bacilli, and remembering the number of respirations performed during the day, each must distribute a large number of these in the atmosphere, especially of crowded cities, where so large a proportion of the mortality is from consumptive diseases.

Taking into consideration the sputum, which, when dried, may be disintegrated and inhaled in our streets, we must admit that if the bacillus is the agent of infection it is a very widely spread one. How are we therefore to account for the comparatively few instances of infection? The evidence of the Brompton Hospital distinctly negatives any idea of its contagion, in the ordinary sense of the word, the number of cases of phthisis occurring among the resident staff being fewer than even at some general hospitals. Also intimate life with a consumptive patient, such as the relations between husband and wife, mother and daughter, to sisters, and members of the same family living together, ought to ensure *certain* contagion; whereas we know this is not so. Some cases are contracted in this way, but they are few in number. I would offer as an explanation that the bacillus requires in every instance a congenial soil to enable it to multiply and to carry on its work. Such soil is to be found in individuals who have been subjected to one or more of the well-known predisposing causes of consumption, such as heredity, bad food, bad ventilation, overwork of mind or body, unhealthy occupations, damp soil, which bring about that blood crisis, or weakness of constitution, which shows itself in various low inflammatory processes, in the exudation of leucocytes, the formation of giant cells, in adenoid hyperplasia, in the tendency to form and exude cells which grow and do not develop into tissue, but die and caseate. The bacillus penetrating to the lungs of such subjects probably sets up centres of inflammation, giving rise to adenoid hyperplasia and the formation of miliary tubercle, and then spreading through the lymphatics it assists in the work of consolidation and destruction. In the walls of cavities it probably finds the best conditions for growth and development—viz., warmth and moisture. People in good health, with sound organs, in full physiological activity, may defy these organisms, and it is probable do inhale them

with impunity. While, therefore, the bacillus must be duly considered in the origin of phthisis, it may be regarded as a more or less exciting cause of the disease, requiring a previous weakening of the constitution to enable it to act. It is, however, possible, if in great numbers and under specially favorable opportunities for multiplication and development, such as are to be found in the hot climates of the South Pacific Islands, that even individuals not predisposed may be attacked, and that the disease may run a particularly short and virulent course.

As to prevention and treatment, the points to be aimed at are: first, the disinfection and removal of the sputum, a measure which was carried out at the Brompton Hospital long before Koch's discovery of the bacillus; the next is the dilution of the bacillus by good ventilation, and its destruction, if possible, by local antiseptic treatment in the form of inhalants, sprays, etc., and to carry this out a number of respirators of different shapes and sizes containing a great variety of antiseptics have been strongly recommended. After prolonged trial of nearly all of these, I have been greatly disappointed with the results. When the antiseptics are combined with some sedative, such as chloroform or conium, the patient often experiences some relief to the cough from wearing such respirators; but by careful physical examinations I have thoroughly satisfied myself that the use of antiseptics in this form exercises no influence on the progress of the disease, while, by a certain extent muzzling the patient, they interfere with the freedom of the respiratory movements which is so essential in the treatment of phthisis. Warm antiseptic inhalations or steam sprays impregnated with these substances, or the fumigating of rooms by dry antiseptic vapors, are not accompanied by this latter objection, and are therefore preferable. Measures directed to the fortifying and strengthening of the constitution, and thus enabling it to withstand the attacks of the bacillus, will be found most effective in the long run, though I would not exclude antiseptic treatment, especially in the form of pure air, pure food, and abundant exercise in mountain climates, which induce more complete development of the organs of respiration.

ON CASES OF BACILLI IN SCARLET FEVER.¹

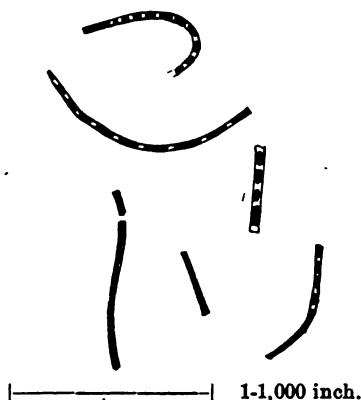

By GEORGE F. CROOKE, M.B. Ed.,

Resident Medical Officer, Leeds Fever Hospital.

THE bacilli figured in the accompanying woodcut were found in the nasal discharge and in the sero-purulent exudation from the inflammatory lymphatic tissue of the neck in certain cases of scarlet fever.

CASE 1, which I will relate because it represents fairly well the type of the subsequent ones in which bacilli were also found, was that of a previously healthy child, four years of age, admitted last autumn on the third, and dying on the fourteenth day of the fever. From its commencement the attack was very severe, and the following are some of the chief symptoms that were observed up to its fatal termination:—A persistent high temperature, which underwent a further elevation just before death, reaching 106° F.; great restlessness and delirium; rash characteristic and well out, but of rather darker hue than usual; injection and swelling of fauces, uvula, and tonsils, the latter ulcerated on their inner aspects; much naso-pharyngeal catarrh, with profuse sero-purulent discharge of a

rather offensive odor—indeed, there seemed to be a general offensive smell emanating from the patient; the cervical lymphatic glands were considerably involved even at this early stage, both sides of the neck being lumpy, but the right more than the left; vomiting was more or less frequent, there was severe diarrhoea, and the urine was

slightly albuminous. One point of clinical interest in the case was the inflammatory condition of the lymphatic glands and tissues of the neck. The swelling gradually increased until it reached that peculiar brawny condition by no means rare in severe cases of scarlet fever. The skin over it was tense and shining, its consistence boggy and semi-elastic, but no fluctuation indicating abscess formation could be felt. I incised the swelling a few days before death, and was struck with the character of the exudation from the wound. It was a turbid, dirty-reddish serum, of offensive odor, and the swelling was seen to be due to an extensive gelatinous infiltration of the tissues of the neck. I at once took some of the exudation on the point of the knife, spread it between two cover-glasses, which I afterwards dried and stained according to Koch's method with gentian violet, mounting them in balsam. My examination of the slides was, I regret to say, only a cursory one, for my attention was occupied with numerous cases of fever in the hospital. But I labelled the slides, and put them away for future examination, which I have made only within the last month or two. On examining the slides with high powers, I found numerous bacilli, as represented in the woodcut; but I will defer their description, and proceed to relate a few other recent cases in which I have found apparently the same organism. For convenience sake I will number them 2, 3, 4, and 5. Clinically all suffered severely from throat symptoms, much nasal catarrh and discharge, considerable swelling of the neck, and constitutional disturbance of a more or less severe form.

CASE 2 died on the thirteenth day of the fever, and the internal condition of the throat, together with the external inflammatory swelling of the neck, necessitated the operation of tracheotomy. She was one whose nasal discharge I examined the day after her admission (third day of disease), and found the bacillus—the long, transverse, curved, and segmented one figured in the woodcut. An offensive odor was noticed about her a day or two after admission; and it was further observed that when the constitutional symptoms ran high the nasal discharge was more profuse, more watery and offensive. I examined some of this fresh watery secretion, and found the bacillus in abundance, but apparently quiescent. I also

¹ Being the substance of a communication to the Leeds and West Riding Medico-Chirurgical Society, read Feb. 2nd, 1883.

examined the blood in this case taken from the puncture of a minute venule, and prepared dried specimens of it according to Koch's method. Bacteria are to be seen—viz., isolated cocci (spores?), the bacterium termo, and small short rods (bacilli); but I could not find anything like the fully developed bacillus seen in the nasal discharge. Immediately after death I examined the swelling of the neck, and found the lymphatic glands and the tissue round about welded into a greyish-red succulent-looking mass, but I could find no traces of purulent infiltration or softening. There were red vascular spots which looked as if they might have broken down had the disease gone on longer. I prepared slides of scrapings from this tissue, placing other portions into alcohol for section-cutting. In all the slides I found bacilli, but they were not so abundantly distributed as in the slides prepared from the first case. In one very good slide it was quite numerous in certain foci. I hope shortly to proceed with the more detailed examination of the organs and inflamed glands of this patient.

Case 3 (sister to Case 2), at present in the hospital, but in a critical condition, gave the bacillus from the nasal discharge, which has been rather profuse the last three or four days.

Cases 4 and 5 are sisters who have had a severe attack with profuse nasal discharge in which the bacillus was found.

In case 5 the inflammation of the neck went on to abscess, which I opened, evacuating bloody and thick curdy pus. I examined this, and found the chain micrococcus in abundance but no bacilli.

The bacillus may be described as leptothrix-like filaments, some straight, some curved, and others bent at an angle, varying in length from 1-1,000 in. to 1-10,000 in., breadth about 1-40,000 in.; some show rod segmentation very distinctly, in others small spore-like bodies are visible, and scattered all about the field are numbers of these spores or cocci. I have never yet found a well-marked zoogloea formation peculiar to the micrococcus; but these cocci, or, I think, spores, are scattered mostly singly or in very small groups all over the field. I have not been able to determine whether there is a distinct sheath. What I took, with dry objectives, to be a sheath, I believe now to be due to diffraction lines. With an excellent Zeiss $\frac{1}{2}$ oil immersion, and, still better, with an equally good 1-16 oil immersion recently forwarded to me by M. Prazmowski, of Paris, I was able, in a few of the bacilli, to make out a faintly stained basis substance of a mucoid character, in which the darkly stained rods and cubical spores were seen to lie. I am not yet prepared, however, to undertake to distinguish this bacillus by its microscopical appearances from every other bacillus, for we know that the various bacilli which of late have been figured and written about—viz., the anthrax bacillus, the bacillus subtilis, leptothrix, the bacillus of pneumo-enteritis of the pig—all resemble each other in general characters, their differences being mainly as to size and character of spores. The bacillus I have described and figured is certainly remarkable for its minuteness, the woodcuts of which were copied from drawings with the camera under a magnifying power of 1,100 diameters. As regards length, they are quite correct, but are, if anything, a shade broader than they actually appeared under that magnifying power.

What I do lay stress upon is the apparent microscopical identity of the bacillus found in the nasal discharge of the patients with that found in the lymph from the inflamed glands and tissues of the necks of two of them. It is sufficient to encourage further researches in this direction, and I hope other workers with similar opportunities in

the same field will before long be able to record the result of their observations. The only check observations I have as yet been able to make are in connection with enteric fever and coryza. In the sputum of the former I found a few filaments of leptothrix, which resembles very much the bacillus from the scarlet fever cases, but is certainly larger; in the nasal secretion from typhoid I could get nothing but the ubiquitous micrococcus in zoogloea formation. In coryza I found cocci in the nasal discharge (of the acute stage), but no trace of bacillus. I myself had a pretty acute coryza, and as I am constantly moving about in an atmosphere of germs, I thought I should most likely find the bacillus, and perhaps I ought to feel comforted with the result of my investigations—namely, that my nasal cavity did not appear to be a suitable nidus for the organism to settle in, notwithstanding the inflammatory condition of the mucous membrane, which is generally supposed to be a condition favorable for the implantation of germs.

I may be asked whether I have examined the urine of scarlet fever patients for the organism lately described as being found there; and in answer to that query I should have to reply practically in the negative. Such observations on the urine of fever patients in a fever hospital must be conducted with great precautions, but in future investigations I shall include the examination of the urine, though feeling a little sceptical as to the results to be obtained. I remember a short time ago examining microscopically a specimen of slightly sanguinous and albuminous urine an hour after it was passed by a scarlet fever patient, and I found it literally swarming with active rod-shaped bacteria, much larger, as far as I can remember, than the ones in the drawing, for they were easily discernible with a power of 250 diameters. The only explanation that I could think of was that the urine had been passed into a utensil containing a residuum of stale urine. The nurse, however, assured me it was passed direct into a urine glass which had just previously been scalded out with boiling water and dried. I should state that I had found organisms in the same urine four hours after it was passed, and in this next observation told the nurse to be careful to get a perfectly clean utensil to receive it and I have no doubt my instructions were carried out. This, then, is the only time I found organisms in the urine of a scarlet fever patient, in the third week, at a time when the pyrexia and constitutional disturbance had subsided; and the explanation of their presence still remains to me a mystery.

Lately, M. L. Bel announced his discovery of the bacillus of measles in the urine of patients suffering from that disease, and about the same time Dr. C. Burger, of Bonn, found in pertussis its special bacillus in the sputum. I have had no opportunity of searching for these organisms as yet, but from the description given of them, while there may be some semblance of the measles bacillus with those I have obtained from scarlet fever, yet the elliptical shape of the whooping-cough bacillus is sufficient to distinguish it. With regard to the nasal discharge in scarlet fever patients, it seems, from a clinical note upon a case communicated to the *British Medical Journal* of Feb. 3rd, by Dr. Tinley, of Whitby, to possess considerable infective properties. It appears from his very interesting communication that a boy suffering from scarlet fever, and treated in a fever hospital, was discharged apparently quite well and free from infectiousness after eight weeks' isolation. About a week after returning home, he appeared to have a distinct relapse, and it was noticed that, in addition to a fresh sore-throat, ulcera-

tion was going on in the nose. Within three days a brother and a sister sickened and developed the fever, and the source of their infection admits of no other explanation than from their brother, who was discharged as convalescent from the hospital, but evidently with mischief still going on in the nasal cavities. It would indeed have been interesting to have examined the nasal discharge from this lad for the bacilli I have described.

I have to thank Dr. Jacob, the visiting physician to the hospital, for his courtesy in placing his cases at my disposal, and also my friend Mr. James Abbott, of this town, whose practical knowledge of microscopy was of great assistance to me when looking over the slides with higher powers.

P.S.—I should mention that the staining fluid used was quite fresh and carefully examined for organisms with negative results, and that similar precautions were taken in using clean slides and cover-glasses.

Leeds.

A Mirror OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Proœmium.

GUYS' HOSPITAL.

LARGE CERVICAL LYMPHADENOMA; [EXCISION; RAPID RECOVERY.

(Under the care of Mr. R. CLEMENT LUCAS.)

For the report of this case we are indebted to Mr. J. D. Hughes.

C. C—, a woman, aged thirty-eight, was admitted into Martha ward on Jan. 8th, 1883, when the following notes were taken:—Her parents are healthy, and both over sixty years of age. She is married, and has five children. There is no tendency to hereditary disease. She has generally had fair health; but during the last seven years she has been subject to rheumatic attacks of short duration, which have not necessitated her lying in bed. These were chiefly rheumatic pains in the shoulders and head, accompanied by nervous headaches.

About fifteen months before admission she first noticed a lump about the size of a walnut, below the left ear and in front of the sterno-mastoid muscle. It was movable and not tender on pressure. It caused her little inconvenience or pain. She applied iodine without benefit and some other applications. Internally she took medicines and cod-liver oil, but without reducing the swelling. She then, finding the swelling gradually increasing, sought advice at the Charing-cross Hospital, with a view of operation, where she remained three weeks, at the end of which time she was discharged, and, it is stated, was told nothing more could be done for her. This was last autumn, since which time the tumour has doubled in size. The patient is a somewhat delicate-looking person of fair complexion, but not very anæmic or emaciated. Her teeth are much decayed, appetite bad, and breath offensive. There is a large mass projecting from beneath and behind the left sterno-mastoid, extending from the lobule of the ear

rather more than half way down the muscle. The tumour measured from above downwards five inches, and from before backwards four inches. It is distinctly lobulated, firm, almost hard, and somewhat tender. There is a lobule in front of the sterno-mastoid, beneath the jaw, about one inch by one inch, and a larger one behind about two inches by an inch and a half. The different lobules are joined together with the exception of one about the size of a walnut situated in the posterior triangle above the left clavicle. The tumour does not swell more one day than another, but of late has been increasing rapidly. There is no enlargement of the lymphatic glands in the axillæ or groins, and the spleen and liver are not enlarged. An examination of the blood was made under the microscope, and some increase of white corpuscles was observed, fourteen white corpuscles being found in a field which with normal blood only showed ten. Mr. Lucas determined to postpone operating till after her menstrual period.

Jan. 16th: The patient being in a better state of health than when admitted, and the menstrual period having passed, Mr. Lucas decided on operating. Chloroform was administered, and the carbolic spray was employed. An incision five inches in length was made along the outer border of the sterno-mastoid, commencing behind the lobule of the ear. A second incision, two inches and a half in length, was then made at right angles to the former, in a direction downwards and backwards. The platysma was divided and the skin retracted by hooks. The small occipital, great auricular, and spinal accessory nerves were divided over the tumour, which was dissected out from under the sterno-mastoid with the aid of the handle of the scalpel and a blunt dissector. There appeared to be no proper capsule to the growth, which was raised with great care from the sheath of the carotid vessels, to which it was adherent. The occipital artery was injured, then seized by two pairs of torsion-forceps, divided, and its ends twisted. The carotid artery and internal jugular vein could now be distinctly seen at the bottom of the wound. The real difficulty which presented itself was how to remove the glands in the submaxillary region without making a fresh incision or dividing the sterno-mastoid muscle. The muscle was well raised by means of a large hook, and the skin in front was then pushed back and invaginated, so as to thrust the glands under the muscle. They were then separated from their attachments and removed. At this time the patient's pulse became very feeble and her breathing shallow, so that it was necessary to finish the operation with rapidity. After the heart had been stimulated by the subcutaneous injection of brandy, Mr. Lucas made another incision, two inches and a half long, just above the clavicle, and having divided the platysma, turned out the last gland, which was about the size of a walnut. The wound was closed with wire sutures, and a drainage-tube passed under the sterno-mastoid into the submaxillary region. A small drainage-tube was also inserted into the wound above the clavicle. The operation lasted an hour and ten minutes.—17th: The patient has suffered a good deal from shock and was ordered brandy during the night. Pulse feeble and compressible. Temperature 97°. She vomited once in the night. The wound was dressed and looked well.—18th: Patient complains of headache and slight pain in the neck. She could not sleep, so was ordered a subcutaneous injection of a quarter of a grain of morphia last night.—19th: She complains of less headache and appears well, though slightly pale and weary-looking. She has a dry throat and slightly furred tongue. Temperature 99°; pulse full, slow, and regular.—20th: Her

bowels being constipated, she was given ten grains of colocynth and hyoscyamus pill. Three sutures were taken out to-day and the drainage-tube removed; the incisions have united primarily; there is no discharge.—22nd: Progressing favorably. Three more sutures were removed. She has a feeling of numbness in her ear.—25th: The remainder of the sutures were removed to-day. There is no discharge. Temperature, pulse, and respiration normal. Has a good appetite. She was ordered quinine and iron in a mixture. Dry dressings are now used over the upper part of the neck, and carbolic spray and gauze over the small wound over the clavicle. The patient has lost all headache and nausea.—30th: Bandages have been dispensed with and the patient gets up daily. There is no discharge, the edges of the wound being entirely healed throughout the whole extent by primary union.

Feb. 3rd: All that is now noticeable is a slight superficial scar where the incisions were made on the side of the neck, and this being behind the edge of the sterno-mastoid it appears as a natural crease. She has no pain in the neck. Her appetite is good, and she has regained color.—5th: The patient left the hospital well.

The tumour removed consisted of a glandular mass six inches in length, and varying in diameter from two inches to two and a half. It was firm and lobulated, the different lobules being strung together. In no part did it show any tendency to caseation or suppuration, and appeared to consist of hypertrophied gland tissue. Some glands were separately removed. The patient's temperature after the operation never once reached 100°.

NEWCASTLE-ON-TYNE INFIRMARY.

OVARIOTOMY IN A WOMAN, AGED FIFTY-SIX; DIAGNOSIS OBSCURED BY OBESITY; RECOVERY.

(Under the care of Mr. PAGE.)

For the following notes we are indebted to Mr. James Limont, senior house-surgeon:—

Mrs. W—, a widow, aged fifty-six years, was admitted September 28th, 1882. She was broadly built, of a fair and florid complexion, had the appearance of robust health, and looked much younger than her age. Her last child was born seventeen years ago, and she had not menstruated for fifteen years. The belly measured fifty-one inches in circumference at the navel, and twenty-five inches from the ensiform cartilage to the pubes. Her only complaint was that she was totally disabled by her unwieldy size, and incapacitated from earning her living as a dress-maker. The anterior surface of the abdomen was dull and the flanks resonant on percussion. There was an obscure fluctuation, as if from some ascitic fluid, and upon sinking the finger deeply downwards between the navel and pubes, as the patient lay upon her back, a tumour could be distinctly felt in the belly. The uterus was normal in size but situated so high up as to be reached with difficulty by the finger. The history of the case was obscure. For the last twelve years the patient had been growing stout, and she was unable to fix the date at which the tumour commenced to grow, or the situation in which it first made its appearance. Twelve months ago she had a severe and, six months ago, a somewhat less serious attack of peritonitis.

On Oct. 5th a small incision was made through fully two inches of fat, and the belly tapped with a trocar. Only a small quantity of ascitic fluid escaped. The incision was enlarged so as to admit the hand into the abdomen, and then the outline of a multilocular ovarian cyst could be traced. No

adhesions of any consequence were detected. The tumour was reduced in size by repeated tapplings, till it could be easily withdrawn. The pedicle was long and slender; it was tied with catgut, and returned into the belly. The wound in the peritoneum was carefully stitched with a continuous catgut suture, and the skin wound closed by means of another continuous catgut suture, a drainage-tube being introduced between the opposing surfaces of fat, but not entering the peritoneal cavity. The operation was performed under carbolic acid spray, and the wound dressed according to Lister. Recovery was uninterrupted, the pulse never having risen above 80.

Remarks by Mr. PAGE.—Diagnosis was rendered difficult in this case by reason of the patient's corpulence, an unusual accompaniment of ovarian disease. Taking into consideration the woman's helpless and uncomfortable condition, her age, her anxiety to be relieved by operation, and the risk she was exposed to of dying from an intercurrent attack of peritonitis, I thought it best to interfere at once, notwithstanding her fatness, and the result tends to strengthen the belief in the soundness of the procedure.

STRANGULATED FEMORAL HERNIA; OVARIAN CYST; OPERATION; DEATH.

(Under the care of Mr. PAGE.)

On Friday, November 10th, a woman, aged sixty-two years, was admitted into the infirmary suffering from pain in the abdomen and vomiting. She said she had been confined to the house for a month in consequence of severe pain in her bowels and constipation. A few days before admission she began to vomit. On the 7th or 8th of November strangulated femoral hernia was diagnosed and preparations made to perform herniotomy, but at the last moment the patient refused her consent.

Having become worse, she was admitted to the infirmary on Nov. 10th. She was then evidently very ill. Her pulse was quick and weak, and her tongue moist, in appearance not unlike olive-colored plush. The abdomen was somewhat distended, tender to the touch, resonant on percussion, and no fluctuation could be detected in it. There was a right femoral hernia, which could not be reduced. It was dull on percussion, not in the least tender, and there was not the slightest trace of any redness of the skin over it. Mr. Page concluded the hernia was not the cause of the peritonitis from which the patient was undoubtedly suffering, but he failed to find any other explanation of her condition. Large warm-water enemata were ordered and one grain of opium was given by the mouth. In the morning she was still vomiting; she had slept, and fecal matter was seen in some of the returned enemata. As her condition was now one of great danger, a consultation was held and a thorough examination made under the influence of chloroform. The result was a unanimous opinion that the hernia was not the cause of the woman's condition. It was also agreed there was a fulness, not a localized, but a general fulness, of the belly, the precise nature of which the tympanitic condition of the bowels made it very difficult to determine, and which was not made out. Mr. Page wished to cut down upon the hernia and, failing to find any explanation there, to open and explore the abdomen; he was averse to cutting down upon the hernia without being prepared to proceed further if he found no strangulation. The injections were ordered to be continued, and one grain of opium with a quarter of a grain of extract of belladonna to be given every four hours. At night the patient was worse, the sickness continued, the injections returned without any fecal matter, and Dr. Arnison concurred

in the view that it would not be rash to cut down upon the hernia, and finding no explanation there to seek for it in the abdomen. The patient, however, refused her consent, and continued to do so until the afternoon of the 13th. Her condition then was one of great prostration. She was vomiting every ten or fifteen minutes, no flatus had passed since the 11th, and the end did not seem to be far distant. Mr. Page cut down upon the hernia and found an enormously thickened sac, almost incorporated with which was the gland usually found in the crural ring. The sac was opened; it contained a few drops of clear fluid only. On passing the finger into the belly it was determined there was no other hernia. The abdomen was then opened, and immediately there welled out from among the distended and intensely inflamed intestines material about which there could be no mistake—the thick tenacious semi-fluid matter commonly found in an ovarian cyst. As quickly as possible the belly was cleared, and then, just emerging from the brim of the pelvis, was found an entire ovarian cyst. It was tapped and removed. The patient rallied slowly but so thoroughly, that on Thursday, the 16th, great hopes were entertained that she might recover. Early on the morning of the 17th, however, the temperature suddenly rose; she began to sink, and died at 4.30 p.m., just ninety-seven hours after the operation. Permission to make a post-mortem examination was refused, so that the precise cause of death is a matter of conjecture.

Remarks by Mr. PAGE.—The circumstances upon which I mainly relied, as evidence that the hernia was not the cause of the symptoms, were the entire absence of tenderness and of any redness of the skin over the hernia. The acute symptoms had existed for probably a week before the patient was operated upon, and even at the time of operation there was no tenderness or redness present. I felt the responsibility of not cutting down upon the hernia, and the more so as I could not advance any definite opinion as to the cause of the serious condition of the woman. Strangulated hernia would have accounted for such a condition as we found her in; but, supposing there was no strangulation, what was the connection between the fulness of the belly and her condition? Possibly a burst ovarian cyst ought to have occurred to us as an explanation, but it did not, and perhaps I may be allowed to state here that it was most difficult to obtain any information about the history of the case previous to admission of the woman into the infirmary. There may have been some injury, bursting the cyst, which the patient wished to conceal. The fact that this aged woman survived for ninety-seven hours two serious operations, performed under circumstances so very unfavorable, is instructive, and should encourage us in even desperate cases to give the patient the chance of recovery surgical interference can afford.

LONDON HOSPITAL.

CASES OF CHOREA ILLUSTRATING SOME POINTS IN THE CLINICAL HISTORY AND ALLIANCES OF THIS MORBID CONDITION, WITH INDICATIONS OF THE BRAIN AREAS MOST COMMONLY AFFECTED; REMARKS.

(Under the care of Dr. F. WARNER.)

CASE 1. *No Rheumatism or Heart Disease; Signs of Rickets in Early Life; the Chorea Movements beginning in the Right Limbs, spreading to the Left Limbs, Face and Palate, the Jaw, and the Eyes; much Paresis.*—Judah S—, aged ten years. The movements commenced in the right arm and leg, subsequently appearing also in the left limbs. The

eyes were very unsteady, fixation never being maintained for more than a few seconds at a time. Lateral movements of the jaws were frequently seen, thus causing grinding of the teeth. Facial movements were very marked; the eyebrows usually worked symmetrically; the zygomas frequently acted asymmetrically; the soft palate was seen frequently jerked up and down; the tongue was much jerked about, and the hyoid bone was often spasmodically depressed; this movement was accompanied by a sucking sound. The intercostal muscles were not choreic, but the diaphragm was occasionally spasmodically depressed. The head was often jerked from side to side. The kind of movements of the extremities varied a good deal. At one time the forearms were held out and supported by an assistant, so that the hands were free, and their movements were only the outcome of the spontaneous action of the brain. The average posture of the hands thus hanging free was the spontaneous outcome of the action of the nerve-centres governing it, and usually presented the wrist drawn over to the ulnar side, a condition of posture not uncommon in hemiplegia from organic disease. There was much separate movement of fingers; this was more marked in the right hand than in the left. The right hand often assumed the "convulsive posture" described by Trousseau as seen in tetany—i.e., the fingers were strongly flexed over the intumed thumb. The boy when at the worst was very weak, lying in the trough of the bed with his head off the pillow, and powerless to raise himself. The skin was dry and harsh.

Remarks by Dr. WARNER.—Here the movements distinctly commenced in the right limbs, indicating the choreic condition of the left hemisphere; later on we have evidence that the right hemisphere was also affected. The eyes were unsteady throughout, a common condition; but, so far as I know, strabismus never occurs from the choreic condition. It may be noted in connection with the facial chorea that the soft palate was also jerky, a not very common occurrence. There was much paresis. We have then a case of brain affection at first almost confined to the left hemisphere; this

Fig. 1.

Right hemiplegia; cerebral facial palsy on right side: the muscles about the mouth are principally affected.

pathological condition was indicated by great weakness of motor power, and by an excessive amount of spontaneous movement. It may now be worth while to point out that of the neuromuscular phenomena here recorded, some are seen in cases of organic brain disease. It was specially noted that though the eyebrows usually acted to-

gether, the zygomatic muscles often acted asymmetrically—i.e., the union between the nerve mechanisms of the two sides of the face appears to have been greater for the upper than for the lower portions. Now, it is well known that many forms of brain disease affect the muscles in the lower part of the face about the mouth, more than those about the eyes (Fig. 1). It appears to me noteworthy that there was "much separate movement of the individual fingers." When all the fingers move together, it indicates that the nerve mechanism of the fingers acts as a whole; when, on the contrary, individual fingers act separately a portion only of that nerve mechanism is active at one time. To those who accept the presence of embolism occurring in a healthy brain as a cause of chorea, it may be said, Did one embolus affect this wide area of brain, or were there emboli all about? Where there successive showers of emboli, as the area affected increased?

CASE 2. *Previous Rheumatism; Mitral Regurgitation; Area of Movements mainly on the Right Side, affecting the Eyes, the Face, the Tongue, and the Depressors of the Lower Jaw.*—John W—, aged sixteen years, was admitted with chorea, which had commenced during convalescence from an attack of acute rheumatism. The movements had commenced in the right upper extremity; he was told of these movements before he was aware of them himself. The area of the movements gradually spread, so that he was unable to walk out of doors when admitted. The movements were almost entirely confined to the right upper extremity. On the day after admission, when the right hand was held out free, the position most frequently seen was the "nervous hand," with the thumb extended (Fig. 2). Under the term "nervous hand," I have described a common spontane-

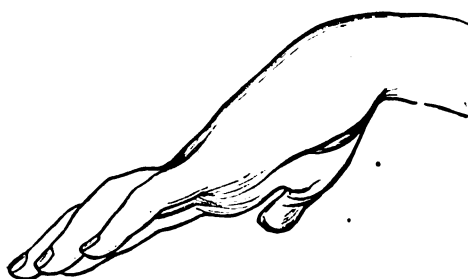

Fig. 2.

ous posture of the hand often seen in nervous children. The forearm being held out, the wrist droops, the metacarpo-phalangeal joints are extended backwards, the internodes being either slightly flexed or kept straight; the thumb is simply extended somewhat backwards, and slightly abducted from the fingers. There were frequent slight lateral movements of the wrist, there was also a considerable amount of movement of the elbow, and some general movement of the whole upper extremity. On other days we saw the fingers often flexed, thus bringing the hand from the "nervous posture" to the "convulsive hand." Different as are the postures of the "nervous hand" and the "convulsive hand," and different as are the probable indications of these postures, they are not separated by any great changes in the relation of parts. If in the "nervous hand" the fingers and thumb are all flexed—i.e., pass from the state of extension to flexion—the "convulsive hand" results. At times he was heard grinding his teeth. This symptom in chorea has not, I think, attracted much attention. Grinding of the

teeth is produced by the action of the pterygoid muscles; these are supplied by the motor division of the fifth pair of cranial nerves, while the sensory fibres of these nerves are widely distributed inside and outside the skull. Teeth-grinding is also very common in various pathological conditions of the brain, organic and functional. The head was frequently moved, apparently owing to the action of the sterno-mastoids and the trapezii. The hyoid bone was seen in frequent movement, and from time to time a sucking sound was made in the mouth, apparently due to movement of the tongue and the muscles forming the floor of the mouth.

Remarks.—The movements were in this case almost confined to the right side, and the grip of this hand was weaker than the left; the paresis and movements were then most marked in the right hand, and it was this weak hand, the seat of so much spontaneous movement, which presented the frequent posture of the nervous hand. It may be assumed that each separate movement is the result of the activity of the motor function of a corresponding portion of the nerve mechanism. If, then, the fingers are often moved separately and individually, it indicates that small portions of the central nerve mechanism are separately and individually in excitation (discharging motor force); if, on the contrary, the fingers are often moved altogether, it in like-manner indicates the simultaneous excitation of a large portion of the nerve mechanism, or the simultaneous and co-excitation of the portions of the nerve mechanism of all the fingers.

UNIVERSITY COLLEGE HOSPITAL.

ANEURISM OF LEFT AXILLARY ARTERY; LIGATION OF SUBCLAVIAN TRUNK IN THE THIRD PART WITH CARBOLIZED SILK CUT SHORT; CURE WITH RETENTION OF LIGATURE; RECOVERY.

(Under the care of Mr. BERKELEY HILL.)

T. W—, a laborer, aged forty-four, who worked usually at heavy lifting, was sent to the hospital by Dr. Gramshaw, of Gravesend. There was no history of rheumatism, syphilis, or of alcoholism. About eighteen months before admission he had felt a tingling from the left elbow to the tips of his fingers. Rather more than a fortnight before his admission he noticed a swelling in his left armpit. This grew in size rapidly, and the pain of the forearm increased, though it never prevented him from working, nor was felt above the elbow.

On admission, on March 9th, 1882, in the left axilla a swelling occupied the whole hollow, pulsating forcibly with the arterial pulse. There was also fullness of the infraclavicular region, where pulsation was also distinct. Though the pulsation of the left subclavian artery was more distinct than that of the right, no swelling could be felt along its course. The left external jugular vein was distended, though it did not fill from below. The left arm could be placed close to the side. The left radial pulse was as full, if not fuller, as the right pulse. Compression of the subclavian quite arrested the pulsation of the tumour. At the heart's apex was a soft blowing murmur. There were no signs of aneurism in the thorax or elsewhere other than in the left axilla. During the patient's stay in hospital the pain in the left forearm ascended to the shoulder, became almost constant, and greatly interfered with sleep.

On March 15th Mr. Berkeley Hill tied the left subclavian artery in the third part, using for the ligature a piece of Chinese silk twist soaked in

carbolic water for twenty-four hours. The ends of the thread were cut off short, and the wound, except for a short drainage-tube at the outer end, was closed with sutures. Until the vessel was tied, the antiseptic spray was not used. During the dressing of the wound the spray was turned on, and the wound well washed with carbolic water. Lister's gauze dressing was applied, and the instruments, operator's hands, etc., well washed in carbolic water before the operation. The pulsation in the aneurism ceased at once on the application of the ligature.

The patient complained of his old pain in the forearm during the night after the operation. The left hand remained warm. On the third day the patient was fairly comfortable; his temperature had not risen; there was no pulse in the radial artery. The pain in the shoulder was felt every night with varying severity. On the 19th the dressings were changed. The wound appeared to have healed by first intention, except where the tube lay. Slight pulsation of the tumour could be detected in the armpit. On the 19th, 20th, 21st, and 22d the temperature rose to 100° or 101°, the highest being 101·8° on the evening of March 21st. It fell to the normal range on the 23rd, and never exceeded that standard afterwards. On the 22nd the dressings were changed, the skin over the infra-clavicular region was red and slightly oedematous, and the drainage-tube was found to be blocked; on gentle pressure three or four drachms of pus welled out. The drainage-tube was replaced a little more deeply, and the dressings again applied. The pulsation in the aneurism was, as before, just perceptible. On the 25th the wound was dressed again. The swelling had much subsided, and the discharge was scanty. The tumour had ceased to pulsate, and there was no pulse in the radial. On the 29th the inflammatory swelling had quite disappeared; the wound was nearly closed; the aneurism was a firm solid mass; there was a very weak radial pulse.

The wound was thenceforth slow to heal. A few drops of pus could be squeezed from the wound at each dressing till April 12th, four weeks after the operation. On the 28th the wound was healed except for a bunch of granulations, the size of a pea, at the angle of the wound. The tumour could be easily made out beneath the pectoral muscles, occupying and filling the infra-clavicular fossa, and lying close against the thoracic wall. Nothing has been seen of the ligature. There is no pulsation in the brachial nor radial arteries.

On May 3rd the patient was discharged at his own urgent request, that he might go to work.

On Jan. 31st, 1883, Dr. Gramshaw (of Gravesend) reported that the patient was very well then; the tumour was still to be felt, without the least pulsation, but not much smaller than in May last and not very hard. The ligature had not come away nor the wound opened since it healed.

LIVERPOOL ROYAL INFIRMARY.

WOUND OF NECK; SECONDARY HÆMORRHAGE; LIGATURE OF COMMON AND EXTERNAL CAROTID ARTERIES; RECOVERY; REMARKS.

(Under the care Mr. REGINALD HARRISON.)

LOUISE B—, aged fifteen, was admitted on October 5th, 1882, suffering from an extensive incised wound of the neck extending downwards for nearly four inches from the angle of the right jaw. The injury had been occasioned the day previously by the patient having fallen violently on a broken plate she was carrying. The wound had been plugged with lint steeped in perchloride of iron.

On admission, Mr. Harrison had the patient placed under ether, and having removed the plug, carefully examined the wound with the view of ascertaining the amount of damage that had been inflicted. Though the carotid artery was bared no wound either in it or in any of the branches of the external carotid could be discovered. A few veins and small vessels were ligatured, and the sides of the wound were then brought together by silver sutures.

Twelve days afterwards when the wound had almost entirely healed, free arterial hæmorrhage was observed to take place. Mr. Harrison was summoned, and on opening the wound, and recognizing that probably one of the carotids had given way, he requested the assistance and advice of his colleague, Mr. Banks. As the hæmorrhage was so free on removing pressure from the bottom of the wound, and the parts were so matted together and obscured by the previous suppuration, it was resolved to tie the common carotid. This was accordingly done with a catgut ligature. This to some extent controlled the bleeding, but it was clear that the hæmorrhage was above that point. The external carotid was then traced up, when a distinct hole could be seen in it about half an inch above the bifurcation. A catgut ligature was placed above and below this opening, when the hæmorrhage entirely ceased, and the patient made a good recovery without any further recurrence of bleeding. As she was going to America in a steamer in which her passage had been booked, she had to leave before the wound had completely closed, but as five weeks had elapsed since the arteries had been tied, no great risk was anticipated.

Remarks.—Mr. Harrison observed that the case was one of considerable interest; it appeared to him that the artery had been opened into by ulceration. The operation was one of considerable difficulty and danger, as the neck was small, the patient enfeebled by the loss of blood, and there was the further disadvantage of having to operate by artificial light in the middle of the night. It was felt that no chance should be thrown away by searching about to determine the precise seat of the hæmorrhage; it was quite clear that one of the largest vessels in the neck was involved. It was therefore determined to place a ligature on the common carotid, as this would permit of breathing time and give a better opportunity for further search. The wisdom of this course was fully sustained by the subsequent proceedings; the hæmorrhage was abated and traced to the external carotid, which was easily ligatured. The completeness of the collateral circulation in the head and neck was well shown in this case; for though the hæmorrhage was distinctly checked when the common carotid was secured, yet it was still sufficient to have caused death in a very few minutes if the opening in the external carotid had not been occluded by a ligature both above and below it. (Mr. Harrison wishes to take the opportunity of thanking Mr. Banks for his assistance in a case of no ordinary difficulty and danger.)

CHESTER GENERAL INFIRMARY.

A CASE OF UNDESCENDED TESTIS SIMULATING INTES-TINAL OBSTRUCTION.

(Under the care of Mr. TAYLOR.)

For the notes of this interesting case we are indebted to Dr. Henry W. King, house-surgeon.

Thomas M—, aged twenty-four, employed as a boatman on one of the Shropshire Union Canal boats, was admitted on Saturday, June 25th, 1881.

On admission, the patient could walk in a bent posture and was in great pain. Upon examination a rounded and slightly reddened swelling of about the size of a hen's egg was found on the left side, over the site of the internal ring, and extending a little above and external to it. On palpation it was felt to be dense and resistant. There was no impulse on coughing; percussion note was perfectly dull. The pain was described as consisting of severe paroxysms coming on suddenly at intervals, and shooting upwards and across the stomach; upon these ceasing, there was left a dull aching pain over the tumour. Expression of face anxious and excited; tongue good; pulse 120, rather full and bounding; respiration normal, but interfered with by an occasional hiccough; urine normal. The patient, upon inquiry, stated that he had always enjoyed good health, but that he had had occasional attacks of pain from the swelling which had existed all his life. He stated further that when troubled with it, after waiting a little, it had always "gone up." The patient stated that he was walking at 4.30 on the morning of Friday, June 24th, when he felt the swelling become gradually bigger, and experienced so much pain that he hardly managed to crawl into the boat. He then went to bed and applied poultices to his side. As he did not feel much better later on, he was seen by a medical man, who tried to reduce the supposed hernia. The pain then became worse. He vomited several times and threw up a quantity of yellowish fluid. He had taken no food since the previous evening. He stated that he was much the same on the 25th. He hiccoughed several times but did not vomit, and the doctor made another unsuccessful attempt at taxis, the patient being under an anæsthetic.

On admission, on the 25th, at 4.30 P.M., he had a hot bath, was then put to bed, and ice was applied over the swelling. Later in the evening he was seen by Mr. Taylor, who ordered four ounces of tobacco enema (B.P.), and the ice to be continued locally as before. At 11 P.M. the symptoms were unrelieved. A more careful examination by Mr. Taylor elicited the fact that the scrotum contained only one testicle, that on the left side being absent. This at once threw new light upon the case, which before had been one of considerable perplexity. It was considered that some inflammation of the testis in the internal ring had been produced, which either mechanically by pressure, or by adhesions, or sympathetically, had given rise to the symptoms of intestinal obstruction. Operative measures were still entertained should the symptoms subsequently warrant it by their increased severity.—12 P.M.: Pain so severe that morphia was administered hypodermically.—25th: Patient the same, symptoms unaltered; to have ice and soda water and milk in small quantities; morphia subcutaneously when necessary.—26th: The patient vomited three times in the night, and had thrown up some bile; hiccough stopped; has passed some flatus by the bowel. Ordered to have half a grain of podophyllin in a colocynth and hyoscyamus pill.—27th: In much the same condition. The bowels had not moved; but some flatus still passes. Tumour softer; skin over it less inflamed. 8 P.M.: A simple enema was administered; and a large evacuation of feces resulted. 11.30 P.M.: A considerable amount of pain still felt. Patient vomited five or six ounces of thick brownish fluid, smelling offensively.—28th: Distinct fluctuation in tumour, which appeared to be rather larger; the vomiting continued as before. 10.30 P.M.: Tumour smaller than in the morning. To have the podophyllin pill repeated.—29th, 8 A.M.: Bowels had acted freely; evacuation of the same nature as the vomit, which has now ceased. 10 P.M.: Tumour

has quite disappeared, and its former site has become resonant.—30th: Patient has passed a good night, and said he felt "quite well."

From this time up to the date of discharge, on July 4th, convalescence continued uninterrupted.

Remarks.—The above case is one of very unusual occurrence and of great clinical interest. It shows that nearly all the symptoms of hernia may be markedly present in a case that is not hernia, or hernia only by imitation. Erichsen, in his "Science and Art of Surgery" (7th edition, vol. ii., p. 664), mentions a case very similar to the above; and Bryant, in the *Medical Times and Gazette* (vol. i., 1872, p. 454), relates a case in which he operated with success, after a consultation had been held upon the patient, a lad of fourteen, and it had been considered probable that (the testis of the affected side being absent) some hernia had descended into the open vaginal process of the peritoneum. This vaginal process was therefore laid open along with the canal, and a quantity of pus evacuated. The peritoneum was found to be thickened, the testis small, and no hernia present. After the operation all the symptoms (vomiting, quick pulse, furred tongue, etc.) ceased, and a good recovery ensued. Mention is made of the subject in Cooper's *Surgical Dictionary* (edit. 1872, vol. ii., p. 697).

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Anophthalmos.—*Clot in Pulmonary Artery.*—*Cancer of Undescended Testicle.*—*Curies of Skull.*—*Visceral Syphilis.*—*Bacillus Tuberculosis.*—*Sulphuric Acid Poisoning.*—*Sarcoma of Kidney.*—*Persistent Ovi-vitelline Duct.*

THE ordinary meeting of the Pathological Society of London was held on Tuesday, February 6th; J. W. Hulke, F.R.S., in the chair. The specimens shown were all of them of considerable interest. Dr. Mahomed tried to raise a discussion on the real nature of the clots in the heart and pulmonary artery sometimes stated to be formed during life, but nothing of much value was elicited in connection with this important subject.

Mr. Godlee showed a living male child, fourteen weeks old, suffering from one-sided Anophthalmos. The eyelids opened for the first time in the seventh week, then some mucopurulent discharge escaped, which got thinner and had almost stopped. The orbit and lids were well formed; no tears flowed from that side; puncta lacrymalia complete; the palpebral fissure opened into a slit lined with the conjunctiva, at the bottom of which was a white patch. The child was in good health; the right eye and lids were normal. Mr. Godlee defended the use of the term one-sided anophthalmos, as associating this condition with that of complete anophthalmos and separating it from cyclops deformity. Up to 1875 only six cases of one-sided anophthalmos had been recorded; three of the patients had died, two having deformity of the brain, but in the third an optic nerve was found and all the orbital muscles were developed. There was no evidence of the presence of the lacrymal gland in his own case.—Mr. Nettleship had seen two other cases very much like this case, one published in the first volume of the Ophthalmological Society's Transactions, in which tears flowed from both orbits; in both of them a "button" was felt under the conjunctiva; and he thought there was something like it in Mr. Godlee's case, and su

gested that the child should be examined under chloroform.—Mr. Boulby said that recently Mr. Willett had a boy, aged eleven, under his care with a similar deformity. The bones had not developed normally, and the palpebral fissure was much smaller than on the other side; he was not sure whether tears were secreted on that side.

Dr. Mahomed showed a Clot from the Pulmonary Artery. He said it was difficult to believe that a clot could be formed during life over healthy endocardium or endothelium large enough to obstruct the cavities of the heart or vessels. Sir J. Fayer had recently described such clots formed in cases of septicæmia and malaria. The only case he had ever seen in which there appeared to him to be evidence of ante-mortem coagulation was the one shown. It was removed from a woman, aged forty-nine, under Mr. Howse's care for epithelioma of cheek; this was successfully removed by operation; afterwards a gland was removed from below the jaw, and three days later she died. At 1.30 she had beef-tea, gravy, fish, and custard pudding. At 2.30 she felt faint, her face became ashy-white, and her lips blue; she recovered, and passed a motion at 3, and another loose motion at 4. She again fainted and became pulseless; brandy and nitrite of amyl were administered, but she died quietly at 4.30. At the post-mortem examination the pulmonary artery was found full of a firm, dark, dry clot, like an ante-mortem clot. The clot pervaded every branch of the vessel on both sides. It was covered by a very thin layer of white lymph-like material; it was quite uniform externally. On making a section a small central clot, with a fine layer of fibrin round it, was seen, which could be squeezed out from the larger clot. There was no other similar clot in any other vessel or either cavity of the heart. Between the vagina and rectum there was a large cyst, and also a dermoid cyst of the ovary. The large cyst contained pus and a number of curiously moulded bodies. The cyst had pressed on the rectum, which contained many dilated veins. At the root of the right lung there was a small pulmonary apoplexy. Dr. Mahomed suggested that an embolus had been carried from the rectal veins to the heart, and through to the left lung, that clotting had spread back towards the heart during life, and that this ante-mortem clot did not fill the vessel, but that the last contraction of the right ventricle filled the pulmonary artery with blood, which then contracted round the smaller clot.—Mr. Hulke said the subject was very large and very interesting, and divided itself into the questions: 1. Were these clots of ante or post-mortem origin? 2. If ante-mortem, were they embolic or autochthonous in nature?—Dr. Norman Moore said that these clots were first noticed soon after the discovery of the circulation of the blood. Polypus of the heart was a common subject of investigation at the end of the last century, and it was then known as a cause of sudden death. In 1793 Matthew Baillie said that these polypi were in truth clots, probably formed after death. He himself had never seen a clot which could be supposed to be formed in the pulmonary artery during life, filling that vessel and reaching into the lungs. He had, however, found large adherent clots in large branches of the pulmonary artery, evidently formed ante-mortem, in cases in which death had not been sudden.—Dr. Morrison referred to a case of clot extending throughout every branch of the pulmonary artery of one lung in which the lung was gangrenous.—He thought this clot had been evidently formed during life, and had been the cause of the gangrene of the lung.—Dr. Hale White mentioned that in November last a man was admitted under his care into the Seamen's Hospital with severe heart disease. Post mortem on

the left side a large clot was found extending from the ventricles to just beyond the innominate artery; the upper part was of a dirty hue, softening and breaking down in the centre; the lower end was clearly post-mortem. Mr. Barker suggested that the very firm clots found in the heart began to form during the last hours of life, and were greatly enlarged at and soon after death. These firm clots were very common in the right ventricle, and were there laminated and adherent, and became softer, darker, and distinctly post-mortem in origin in the pulmonary artery.—Dr. Williams asked if there were two layers of decolorized clot in Dr. Mahomed's specimen, and if so, how he accounted for the formation of the outermost layer of fibrin?—Mr. Sutton said that in cases of cancer in which death was very slow, it was possible to predict with certainty the presence of a large clot in the pulmonary artery.—Mr. Boulby said Dr. Mahomed had not showed that his clot was embolic; he had not proved that the rectal veins contained any clots, and even if they did, clots were not displaced from veins except from some change in the walls of the vessels. He therefore could not accept the embolic origin of this clot as satisfactorily established.—Mr. Lockwood said that even assuming that a piece of clot had been detached from a clot in a rectal vein before passing to the lung, it would have had to pass through the liver capillaries, and this rendered it almost impossible for Dr. Mahomed's suggestion to be correct.

Dr. Mahomed replied that he thought in Dr. Morrison's case the gangrene was primary, and the clot in the artery secondary. He asked Dr. White whether in his case there was any disease of the aorta. The rectal veins were not examined, and he suggested that the embolus was very minute and carried to one of the extremities of the pulmonary vessels. At the lower end of the rectum the portal and systemic veins communicate, and so an embolus could pass from them into the heart without going through the liver.

Dr. Mahomed also showed a specimen of Cancer of an Undescended Testicle. He said that undescended testicles were known to be very prone to malignant disease, as shown many years ago by Dr. G. Johnson and Mr. Arnott, among others. This case was under Dr. Moxon's care at first and then under his own. For six weeks before admission the patient had pain in the right lumbar region, and a swelling in the hypogastrium had been noticed for three weeks. The swelling was like that of a distended bladder, and moved with the bladder; it was semi-fluctuant, and was therefore tapped, and a little whitish material was found in the cannula and proved to be sarcomatous tissue. No sign of any secondary infection was discovered. Mr. Howse then examined the case, but finding the man's leg swollen, refused to operate. At the post-mortem the tumour was found hanging over the side of the pelvis by a small thin pedicle, consisting of the cord, and it could have been removed during life with the greatest ease. Secondary growths were found in the lumbar, retro-peritoneal, mediastinal, and bronchial glands. The enlarged glands had caused great distension and ulceration of the duodenum. The ducts of the liver were greatly distended. Microscopical examination of the liver tissue did not show that it was inflamed, as might have been expected. The thymus gland was also infected. The tumour tissue was that of an ordinary carcinoma.

Dr. Norman Moore showed a specimen of Ulceration of Calvaria, from a man, aged forty-two, who died in St. Bartholomew's Hospital from abscess of the brain. The scalp was entire, but for many months it had felt puffy all over. When removed there was found a quantity of pus with some loose

fragments of necrosed bone and a large quantity of greyish oedematous granulation tissue. The calvaria was ulcerated over its whole outer surface with many small areas of necrosis, and it could be cut with a knife. On the inner surface were some ulcerated and necrosed patches. The dura mater was entire, but beneath it, on the posterior part of the right cerebral hemisphere, there was a superficial abscess of considerable size, which extended through the grey matter, but not deep into the brain. All the viscera were free from amyloid infiltration and from gummata, and Dr. Hensley, who had treated the case, could discover neither specific indications in treatment nor the history of a sore. Such calvariae were usually due to syphilis, but were they invariably so?

Dr. Norman Moore also showed specimens illustrating Visceral Syphilis, from a man aged fifty-six, who died in St. Bartholomew's Hospital. In November, 1881, he was admitted with hæmatemesis and ascites, and was concluded to have cirrhosis of the liver. He partially recovered, and went out in March, 1882. In January, 1883, he was readmitted with ascites, and died shortly after of a general dropsy. There was a distinct history of syphilis and a well-marked scar. His viscera showed three forms of morbid change attributable to syphilis: 1. The whole capsule of his liver and that of his spleen were evenly thickened, while in the liver scar-tissue in several places dipped down into the organ. The spleen weighed nineteen ounces. With this great peri-hepatitis there was no general thickening of the peritoneum. 2. The kidneys gave a well-marked amyloid reaction. 3. The aorta was extensively calcified, and showed two large aneurismal dilatations, one at the end of the arch and the other a little above the diaphragm.

Mr. Hulke, in reference to the first case, asked what occupied the spaces left by the destruction of the bone. In regard to the second case, he said that the true Hunterian sore did not leave a well-marked scar in many cases, the best-marked venereal scars being caused by the large sores of simple origin.—Mr. Barker said that he had seen caries of the parietal bone without any history of syphilis, in a case in which there was also caries of the spine. In this case the caries had occurred on the inner surface of the parietal bone. The patient was a boy. On trying to strip off the dura mater a layer of caseous material was found between it and the dura mater; the bone was excavated to a depth of about a line.—Mr. Doran observed that it was important that the significance of peri-hepatitis, as found in the autopsy of a patient who had never shown any symptoms of hepatic disease during life, should be clearly understood. As yet nothing was certain on this point. Mr. Doran had made a large number of necropsies of patients who had died with uterine or ovarian tumours, or after their removal. In such cases adhesion of the capsule of each kidney was the rule, though a history of renal disease was the exception. Yet he had never observed peri-hepatitis, except where recent general peritonitis existed, or where the history of the pelvic tumour had shown some suspicion of hepatic complication.—Mr. Morris said that it was necessary to guard against excluding syphilis simply on account of absence of a syphilitic history. He related a case of long-standing caries of the lower jaw, in which he quite failed to get any syphilitic history, but which resisted all but anti-syphilitic treatment.—Dr. N. Moore said that under the scalp there was a large amount of pus. The man had been treated by anti-syphilitic remedies without benefit. There was a distinct history of constitutional syphilis in the second case.

Dr. Samuel West described two cases of rapid

Phthisis, in which he had obtained from the contents of cavities bacilli in great groups and masses, in one case so large as to be visible to the naked eye. One case was fatal in ten weeks, occurring in a previously healthy man; the other was of seven months' duration, but ended rapidly. Both had extreme constitutional symptoms of high temperature (102° to 103°), rapid pulse, and rapid breathing, with great prostration and emaciation. In one case numerous sections of lung were made, but bacilli were not found in the lung tissue, but only in the lining of the cavities. The fact was important, as indicating the value of the number and arrangement of the bacilli in the sputum of phthical cases. He thought they were evidence of disintegration of the lung, of slow destruction if few and isolated, of rapid destruction if numerous and in groups or masses. Great variations would occur then in the same case from time to time, as the contents of the cavities were expectorated in greater or less abundance. Dr. West stated that the results of his observations upon a large number of cases of phthisis (at least fifty) led him to the conclusions:—1. That bacilli were found in all cases of phthisis in which there was excavation, and that they varied in number with the rate of destruction. 2. That the arrangement in groups and masses indicated greater destruction than if the bacilli were isolated, unless the isolated bacilli were in great numbers. 3. That he had detected no variation in the size of the bacilli in different cases. It has been stated that the bacilli are smaller and less completely developed in the very rapid cases than in the more chronic cases; but Dr. West's observation did not confirm this. 4. That in many of the rapid cases bright bodies existed in the bacilli, which had been called spores; and that in some of his cases similar bright bodies existed free in the preparation. Were these free spores? 5. That the bacilli being in his opinion evidence of destruction of lung, they might, in some doubtful cases, be of diagnostic value; but that in most cases they were merely an additional confirmation of what was already clear from the clinical and physical signs, and the same was true as regarded prognosis.—Mr. Alban Doran asked whether Dr. West thought that the more broken-down tissue there was in the lung the more bacteria were present, and, if so, was it not probable that the micro-organisms were secondary to the disease in the lungs? In dental caries the micro-organisms were more numerous the more abundant the decomposing albuminoid matter clinging to the tooth.—Dr. Goodhart asked Dr. West whether by phthisis he meant only tubercular disease, or all destructive diseases of the lungs.—Dr. S. West said that he meant by phthisis cases of "consumption," beginning at the apex and running the usual course; he supposed they would be called tubercular. He had not found the bacilli in non-consumptive cases of lung disease. He did not wish to speak with certainty as to the etiological importance of the bacilli.

Dr. Hale White showed a recent specimen of Sulphuric-acid Poisoning. Thirteen hours before admission to Guy's Hospital a woman took a large quantity of sulphuric-acid, and she died collapsed. The mouth was excoriated and inflamed; the aryteno-epiglottic folds were reddened, and had a slough on them; the œsophagus had a large slough on it; the stomach was inflamed and blackened in places; the duodenum was healthy, showing that the acid had not passed into it; the transverse colon was intensely inflamed. Thus in thirteen hours the inflammation had spread through the stomach to the transverse colon; the liver was of a peculiar whitish-yellow color on the surface, and he asked whether this could have been due to the

escape, through a perforation in the stomach, of mustard given as an emetic.

Mr. Knowsley Thornton showed a specimen of Sarcoma of the Kidney removed by operation. The tumour began six years ago, and was then movable; it was very soft, brain-like; mixed in character. The patient was a woman fifty-three years of age, and the tumour was inconvenient from its size. The tumour weighed eleven pounds; it was removed on Feb. 2nd, and the patient, up to the present time, was doing well. The kidney itself was healthy, and the tumour evidently sprang from the capsule. From the detection of resonance behind the dull tumour he had diagnosed it as an ovarian growth, and had removed it through the middle line.

Mr. Barwell showed a specimen of Persistent Ovi-vitelline Duct, causing Intestinal Obstruction. The patient was a boy, aged ten; he was brought to Charing-cross Hospital with symptoms of acute intestinal obstruction. The bladder was found distended, and was emptied by catheter. Enemata were administered, and opium and atropine given. On Feb. 5th the abdomen was opened, and the finger then felt a hard, tight body passing from the middle of the abdomen to the right iliac fossa; it was found attached to the umbilicus; on incising it, solid fecal matter came out. Recognizing it as a persistent ovi-vitelline duct, it was tied in two places and divided. The boy died in thirteen hours, and it was found that the diagnosis was correct. He was not aware of any case in which the ovi-vitelline duct had caused intestinal obstruction.

Dr. Mahomed showed two card specimens (1) Paravaginal and Dermoid Cysts from a case of Pulmonary Thrombosis; (2) Dilated and Ulcerated Duodenum, with Dilatation of Hepatic Ducts from Pressure of Cancerous Glands.

Aneurism of the Aorta.—Sarcoma of Femur.—Chondroma of Jaw.—Deformity of Humerus.—Disease of Bones in Animals.—Osteitis Deformans.—Rickets.

The ordinary meeting of the above Society was held on Tuesday, February 20th, Mr. J. W. Hulke, F.R.S., in the chair. Among other specimens shown, were several illustrating disease of bones in the lower animals.

Mr. Butlin read the Report of the Morbid Growths Committee on Dr. Haddon's case of Disseminated Sarcoma. Dr. Cobbold had been consulted by the committee and was of opinion that the disease in the kidney might be parasitic, bodies resembling psorospermial sacs being found. In the heart the disease was not parasitic, but probably sarcomatous.

Dr. S. West showed a specimen of Aneurism of the Arch of the Aorta opening into the Pulmonary Artery. It was obtained from a man, aged thirty-eight, who was seized suddenly with pain in the chest, cough, and dyspnoea. On admission into hospital, his cardiac dulness was found increased, and a murmur, loudest in the third left costal space, was heard, conducted in all directions. He died from gradual cardiac failure. The heart was enlarged, the right ventricle much dilated. Just above the pulmonary valve a hole, half an inch across, was found; the pulmonary valves were healthy; the hole led into an aneurism of the aorta the size of a hen's egg. The rest of the aorta was atheromatous. It was very rare for an aneurism to burst in this direction.

Dr. West also showed an Aneurism from the Second Part of the Arch of the Aorta, in which death occurred from aortic embolism. The patient

was a man, who suffered from cough, dyspnoea, and dysphagia. The diagnosis of aneurism was made. He suffered from several severe paroxysms of dyspnoea, in one of which he fell back dead. At the autopsy a sacculated aneurism, springing from the top of the arch, was found reaching up in front of the trachea between the two carotid arteries; the left recurrent laryngeal nerve was wholly adherent to the sac. Lying curled up in the arch was a decolorized laminated clot, which was found to have come from the left ventricle; it was flattened and like clots found in the ventricle in such cases. This termination of such a disease was an extremely rare one.

Dr. Silcock showed an Aneurism of the Abdominal Aorta springing from the back of the Artery opposite the superior mesenteric artery. It formed a huge sac behind the peritoneum, containing seven pounds of clot. It had burst into the sheath of the left psoas and formed a fluctuating tumour in the left groin. It had also spread to a less extent into the right psoas. The vertebrae were eroded, and the dura mater was exposed. A similar case occurred under the care of Sir Wm. Fergusson, in which he tied the femoral artery. The whole of the viscera were pushed forward. The man complained of pain in one hip-joint, due to pressure on the lumbar plexus. The diagnosis of malignant disease was made. The skin was not discolored. There was no evidence to show when the rupture occurred. The man had been ill two years. Some of the clot was evidently of very old date.—Dr. S. Wilks asked Dr. S. West for more particulars of the bruit in his first case. He had seen two or three similar cases, two of which were diagnosed. The bruit in both was diastolic, and very characteristic in its position and character.—Dr. Taylor asked if the acute symptoms just before death were supposed to be due to the rupture of the aneurism into the pulmonary artery. In a case he had published the rupture did not take place just before death, as was shown by the thickened edges of the opening, and the artery opposite it. He had had another similar case under his care recently, in a man aged thirty-nine, who, on admission to the hospital, suffered from dyspnoea and consolidation of the right base of the lung; a systolic murmur at right base, a diastolic murmur, and a pericardial rub at one time were detected. There was also localized dulness at the upper part of the sternum. After death an aneurism one inch in diameter was found springing from the aorta, bulging over and opening into the pulmonary artery; opposite the opening the pulmonary artery was thickened, suggesting that the current of blood had impinged upon this part of the vessel. This condition was not diagnosed during life. A similar case occurred in Guy's last August, and he thought a good many cases of this lesion could be collected.—Dr. S. West replied that there was no evidence of the rupture having occurred in the four weeks while the man was under observation, but his illness dated from a sudden onset ten weeks before that, and he thought the rupture occurred then. During life the diagnosis of aortic aneurism was made; a thrill was felt in the third and fourth left spaces. There was a loud double murmur, loudest at apex and left base, propagated from left base to lower end of sternum; it commenced at the latter end of diastole and continued all through the systole.

Mr. Arthur Durham showed a boy, aged nine years, who was admitted into Guy's in September last. Five or six months before he hurt himself in the leg and thigh, and then a swelling in the upper part of his thigh was first noticed, which had rapidly increased; the pain, at first great, subsided. In September the thigh measured twenty-

four inches round. He thought it a large, very rapidly spreading osteo-sarcoma growing from the inside of the bone. The tumour was now of enormous size, involving the whole length of the bone.—Mr. Hulke said the case was of great interest, but as it would probably soon come before them again in another form, discussion had better be postponed.

Mr. G. Lawson exhibited a Recurrent Cartilaginous Tumour of the Head and Neck. The patient had had the growth removed eleven times, five times by the late Sir William Fergusson, and six times by Mr. Lawson. She first came under Mr. Lawson's care in December, 1877, and he then removed a large cartilaginous tumour, which nearly filled the mouth and a large portion of the lower maxilla. Since that time there have been five operations for extensive recurrences of the disease, and on each occasion masses of cartilage similar to those exhibited were removed. The recurrences have been in the neck, and in the temporo-maxillary region, extending from the glenoid fossa of the temporal bone towards the base of the skull, and in the cheek between the mucous membrane and the external integument. At each operation the tumour was found to be composed of large isolated masses of cartilage, varying in size from that of the closed fist to a small nut, packed tightly together, and each portion enclosed in a distinct capsule, from which it could with a little difficulty be enucleated. The specimen exhibited was removed on Feb. 10th of this year, and the patient is again rapidly progressing towards recovery.—Mr. Hulke did not know of any instance of a pure enchondroma recurring again and again. This did not seem to have been a case of a typical enchondroma. Chondro-sarcomata often recurred. He referred the tumour to the Morbid Growths Committee.—Mr. Barwell asked whether this case did not show the propriety of removing half the lower jaw from the articulation in all such growths.

Mr. Butlin was glad the case was to be referred to the Morbid Growths Committee, as Dr. Thin, who had examined the growth, evidently had difficulty in deciding whether it was a pure chondroma or chondro-sarcoma. It was interesting also to notice that it grew from the outer surface of the periosteum. He had removed a para-osteal tumour of the radius without excising any of the bone. A slow recurrence was afterwards removed, and now the patient was free from disease. Had the disease grown from under the periosteum, the only proper treatment would have been amputation of the forearm.

Mr. Lockwood showed a specimen from a female body brought into the dissecting-room. Growing from the lesser tuberosity of the humerus was a process of bone an inch long, to which the infraspinatus was attached. The question was, whether this was a congenital abnormality of the bone or due to injury. Congenital deformity of this nature was very rare. There was some evidence of rheumatoid arthritis. The other humerus had evidently been fractured.—Mr. Barwell said the appearance was like that of ataxic arthritis.

Mr. Sutton showed six specimens of bone disease in animals. The first was a skeleton of a Lizard from the Zoological Gardens; it had lived there two years, and had been fed on eggs and fruit. The costal cartilages were distorted in the middle of the cartilages. A layer of ossifying cartilage existed normally between the articular cartilage and bone in this animal; but in this case there was a quantity of soft matter above this ossifying cartilage; the marrow was soft; compact bone very thin, cranial bones very soft. On the cornua of the hyoid bone were four cartilaginous tumours. The second was a skeleton of a Rhea.

The bones were mere shells filled with oily material, so soft that they could be twisted in any direction like leather. This bird, too, had at the junction of the epiphyses of two metatarsal bones two large cartilaginous tumours. Four skeletons of Monkeys were also exhibited. One was said to be a paralyzed monkey. The chest was deformed, but without the costal beadings seen in rickets. The crests of the ilia were doubled over by the abdominal muscles. The serratus magnus had produced the same effect on the base of the scapula. The long bones were very soft at their ends, and the epiphysal cartilages enlarged. The bones were also curved at the lower end, where the cancellous tissue was specially soft, and contained fat. In one femur the medullary cavity extended quite down to the epiphysal cartilage. The skull showed some osteophytic bones. In the second specimen the chest was deformed, the long bones only distorted at the lower end. The skull in the roof of the orbit and at the posterior fossa showed most marked cranio-tabes, even to perforation. The third showed osteoporosis. It was sound, except in the skull; there was no deformity. On section of the skull the condition was at once discovered. In the fourth specimen there was slight lateral curvature of the spine. The left radius was curved in a very peculiar manner, which he called osteitis deformans. Only it and the ulna were diseased. He had concluded, from his dissections of monkeys, that osteomalacia, osteitis deformans, osteophytes, and rickets were all results of chronic inflammation. He thought the pathological processes were but modifications of the physiological developmental changes in the bones. These were periosteal deposit, osteoporosis, and epiphysal growth. Irregular periosteal deposit led to osteophytes; excess of it to osteitis deformans. Excess of osteoporosis led to osteomalacia, and excess of epiphysal growth was the change in rickets. But all were caused by chronic inflammation.

Mr. Bouly showed the Femora from two cases of Osteitis Deformans. W. H.—, aged sixty-four. There was a very marked curve forward of the right femur; curve equally distributed over the length of the bone; the compact bone of the shaft was much thinned. A soft mortar-like substance filled up the medullary cavity. A small cavity full of cheese-like material was found near each end of the bone. In the second case, the right femur had become curved during the last ten years of life, the whole bone curved out and forwards, enlarged in circumference, rough externally, articular surfaces normal, medullary canal irregular, compact tissue thickened; a small cavity near the front of the bone contained a small sequestrum. The two bones differed in all points except the curve and increase in diameter. He thought in each the cause was inflammation of the bones. Lengthening of bones occurred from excess of blood-supply, but did not cause a curve except in the tibia. The soft mortar-like material he thought due to degeneration of inflammatory products. The almost entire absence of an outward curve in the first specimen was of interest, as in all other cases he had seen this had occurred.

Mr. Barwell showed two children, to illustrate the formation of the curves in Rickety Bones. W. P.—, aged eight, in whom one tibia was thickened and an inch longer than its fellow, the bone was bent forwards and was becoming more bent; it was due to hyperplasia affecting the front more than the back of the bone. Sarah A.—, aged four years and a half, a strong child except for signs of rickets. The right tibia was more bent than the left, and was becoming more bent even though she was kept in bed; it was considerably longer

than the other—an inch and a quarter, measured along the curves. There was evidently, therefore, a hyperplasia of the bone, affecting the front of the bone most; sometimes the front of the bone was tender. He submitted that rickets did not connote merely softened bones, but that the curves were produced by localized hyperplastic inflammation of bones. Other diseases besides rickets caused tendencies to bony curves in children. He referred to a man, aged twenty-two, in whom the bones were found, in performing osteotomy, soft enough to be cut with a knife. This man was well till five years of age, when he had a fever; then the bones began to bend; he had genu valgum, tibiae were not bent, patellae dislocated on to outer condyle of femur, left radius very twisted, and in the convexity he has pains. This was certainly not rickets, but a disease for which we had no name.—Mr. Hulke said Mr. Sutton's specimens were very interesting, and particularly as they all occurred in animals living in unnatural conditions of life tending to produce general malnutrition.—Mr. Parker said these cases were instances of true osteomalacia, as the disease was called generally. Typical osteomalacia had been produced in animals by giving them food deficient in lime salts. He thought we had no proof that normally there was a periosteal deposit, which, when irregular, produced osteophytes, or in excess caused osteitis deformans. He had always regarded osteophytes as disease of bone, not of the periosteum. He thought that osteoporosis in the skull was very common in young children. He could not regard rickets as epiphyseal overgrowth merely.—Mr. Treves questioned whether Mr. Sutton's nomenclature aided us at all. What evidence was there that his specimen of osteoporosis was due to chronic inflammation rather than to malnutrition? And further, how could he show that osteomalacia was an excess of osteoporosis?—Mr. Eve remarked that all Mr. Sutton's specimens were diseases of development, whereas osteomalacia and osteitis deformans were diseases of later life. In reference to Mr. Barwell's cases, he pointed out that in rickets the greatest formation of bone occurred in the concave surface of the bone; but in some cases the bone was found heaped up in the convexity.—Mr. Sutton was assured that all pathological processes were but exaggerations of physiological processes. In osteoporosis the sign of chronic inflammation was increased vascularity. On examining the bone microscopically, spaces filled with fat lined by osseous tissue or decalcified bone were found. He would submit his specimens to a committee of the Society.

Dr. Carrington showed as a card specimen an Aneurism of the Aorta. There were two aneurisms, one springing from the first part of the arch, which was nearly occluded by clot. The other, much larger, sprang from the second part of the arch, and although containing a large quantity of clot, had yet caused death by pressure upon the trachea at its bifurcation. The patient had been treated by rest, dieting, and iodide of potassium.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Ligature of the Common Carotid Artery for Aneurism of the External Carotid.—Ligature of the Right Subclavian and Carotid Arteries for Aneurism of the Aorta.—Aneurism of the Arch of Aorta involving the Innominate Artery.—The Distal Ligature.

THE ordinary meeting of this Society was held on February 13th, Professor Marshall, F.R.S.,

President, in the chair. Three papers were read dealing with the subject of aneurism. Mr. Heath's was the record of a case in which the common carotid was tied for an external carotid aneurism in a patient suffering from cardiac disease, and death occurred from cerebral embolism, due to the endocarditis, seven weeks after the ligature, the aneurism itself being filled with clot. The papers by Mr. Marsh and Mr. Morris both dealt with the question of distal ligature in cases of aortic and innominate aneurism, and the prolonged debate which ensued was mainly occupied with this important subject. Several museum specimens in illustration of the subject were shown by Mr. Morris and Mr. Heath. Microscopical preparations showing the changes induced by silk and catgut ligatures respectively, were exhibited by Messrs. Stanley Boyd and Horsley. The last-named gentleman also demonstrated the comparative strength of ox aorta tendon and sciatic nerve. Mr. F. T. Paul, of Liverpool, exhibited microscopical specimens from the case of scirrhus of the prostate related by Mr. Harrison at the last meeting. As doubts were expressed at that meeting as to the cancerous nature of the tumour, Mr. Paul was anxious that the Fellows should have the opportunity of seeing the growth, which clearly started from the glandular epithelium of the prostate.

The following is an abstract of the paper on a Case of Aneurism of the External Carotid Artery; ligature of the common carotid, with cure of the aneurism; death from paralysis on the thirty-fifth day; by Mr. Christopher Heath. The author records this case in support of the view that ligature of the common carotid is sufficient for the cure of certain cases of aneurism of the external carotid, and in opposition to the view that ligatures should also be placed on branches of the external carotid artery. A carbolized silk ligature was employed with antiseptic dressings, and the wound healed by first intention, the silk being *in situ*. The patient was a young woman of twenty-three, with extensive disease of the cardiac valves. A month before admission she came down in the morning speaking indistinctly, and found that the tongue deviated to the right side. Four days after she noticed a swelling near the angle of the jaw, for which she became an out-patient at a hospital, where the swelling was painted with iodine. On admission to University College Hospital there was a smooth, round, pulsating swelling, just below the right mastoid process, reaching down to about the level of the upper border of the thyroid cartilage, limited in front by the ramus and angle of the jaw, and overlapped behind by the sternomastoid. The right tonsil was pushed somewhat inwards, and the tongue deviated much to the right, the right half of the organ being a good deal wasted. The heart's impulse was strong and heaving, extending far outside the nipple-line. At the apex a loud, well-conducted, mitral systolic murmur was heard; at the base a much fainter double aortic murmur. On Jan. 11th, Mr. Heath tied the common carotid above the omo-hyoid with a carbolized silk ligature, the ends of which were cut short and the wound closed throughout. An antiseptic dressing was applied after the wound had been washed out with carbolic lotion. A gutta-percha splint was bandaged to the head and shoulders to keep the face turned towards the left. Slight pulsation persisted till the seventh day, on which the wound was found completely healed. The patient made a good recovery until the thirty-third day, when, while eating dinner, she suddenly dropped her knife and fork and complained of pain in the spine. An hour and a half later her speech became unintelligible, and four hours later she ceased to take notice. During the night swallow-

ing became difficult, and next day (thirty-fourth) the right arm, and soon after the right leg, became paralyzed, and she died on the afternoon of the thirty-fifth day. The post-mortem showed an embolus at the base of Broca's convolution, and five or six small patches of yellow softening were found beneath the grey matter of the surface. The heart was much hypertrophied, the mitral valve thickened, and with vegetations on both surfaces; each cusp of the aortic valve was also studded with vegetations. The wound was completely healed, and the sac of the aneurism filled with firm clot. It sprang from the external carotid half an inch above the origin of the artery, stretching the hypoglossal nerve, which was of a yellow color at that point. The silk ligature was embedded in connective tissue, and a firm red clot extended for three-quarters of an inch above and a quarter of an inch below the ligature. Microscopic examination showed the silk to be unaltered.

The next paper read was on a Case of Ligature of the Right Subclavian and Carotid Arteries for Aneurism of the Aorta; death from rupture of the sac on the fifty-first day after the operation; by Mr. Howard Marsh. F. B.—, a shopman, aged thirty, was admitted into St. Bartholomew's Hospital, Jan. 17th, 1881. Previous health good, and never had syphilis. Was in the habit of lifting heavy weights, but was unaware of having received any blow or strain. Nine months before admission he had "neuralgia" in the right side of the head and neck, and in the right shoulder and arm. A month later his voice changed to a hoarse whisper. Seven weeks before admission he first noticed a pulsating swelling at the root of the neck to the right of the middle line. This was of the size of a bantam's egg. On examination the tumour was found rising above the right sterno-clavicular articulation. The clavicle and sternum were partially absorbed. No pressure signs or extended dulness could be detected in the thorax; no bruit; heart normal; pulse in the right radial somewhat more feeble than in the left; pulsation hardly to be felt in the right carotid; pupils equal. In the next few days the swelling increased slightly towards the left. On Jan. 31st the subclavian and carotid were tied with catgut prepared by the chromic-acid process. The wounds did favorably, but the operation was followed by rapid enlargement of the aneurism to the left side; the swelling soon led to absorption of the sternum, and extended high in the neck. Repeated hæmorrhages occurred, and the patient died at the end of about seven weeks. The author remarked that the case illustrates what is probably a serious danger in the treatment of aortic aneurism by ligature of the carotid and subclavian vessels—namely, disturbance of the blood pressure and consequent dilatation of the arch in some new direction, and he alluded to one case in which great pulsation in the sac followed the operation, and to another in which a second aneurism was found, which had apparently commenced very shortly after the trunks had been tied. In the present case no post-mortem could be obtained. He believed, however, the aneurism was originally seated on the first part of the arch near the innominate, but that increased pressure after ligature led to rapid dilatation of the arch towards the left side.

A third paper was read, on a Case of Aneurism of the Arch of the Aorta involving the Innominate Artery, with remarks on the Distal Ligature, by Mr. Henry Morris. A married woman, aged forty-three, who described herself as a "farm laborer," came under treatment on Sept. 7th, 1882, for an aneurism supposed to be of the innominate artery. The symptoms were partly characteristic of innominate, partly of aortic aneurism; but the shape

and position of the tumour favored the opinion that it was chiefly, if not entirely, of the innominate vessel. Tufnell's treatment was tried for nearly two months with temporary benefit. As distal pressure on the common carotid produced marked effect on the aneurism, and pressure on the third part of the subclavian did not, ligation of the carotid alone was decided upon. The operation disclosed a strongly pulsating internal jugular vein adherent to the sac of the aneurism, but no common carotid could be found. In the search for the artery the vein was wounded and had to be ligatured above and below the wound. The patient died fourteen days after the operation from asthenia, the result of diffused suppuration in the right side of the neck. Post-mortem examination showed the aneurism to be almost entirely aortic, though the innominate and roots of the subclavian and carotid were thickened and enlarged. The carotid was firmly occluded by a plug of fibrine about one inch and three-eighths of an inch from its origin, and lay flattened and deeply bound down by a dense thick layer of sclerosed connective tissue, out of which it was dissected with much difficulty. The left innominate vein was occluded, so that the whole of the blood from the head had to return through the right external jugular and other smaller anastomosing veins of the right side; this had excited the fatal suppuration. The case showed:—1. The impossibility of diagnosing some aortic from innominate aneurisms. 2. The unreliability of any conclusion which may be drawn from the effects of distal compression on the large arteries in connection with such aneurisms, as to the form of operation to be adopted for their cure. 3. That a very appreciable pulsation may be felt along the course of the carotid in the neck, though that vessel be plugged, if the internal jugular become incorporated with the wall of the aneurism. 4. That it is not probable that this aneurism would have been cured by the occlusion of the subclavian as well as the carotid. It is suggested that Mr. Heath's well-known case has led to the double distal ligature being held in a far too favorable light, and that in estimating the effect of this treatment too much importance has perhaps been attached to cases, such as Fearn's and others, in which the aneurism has been found filled with clot after death. As distinct from the effects of ligature, much importance ought also to be attached to the condition of the blood and the circulation which precedes death, as well as to the slow approach of death, circumstances which themselves favor, in no small degree, the deposition of fibrine. In suitable cases of aortic aneurism ligation of the left common carotid gives the patient a much better chance, because the method is more nearly allied to Brasdor's, whilst there is only half the risk of the double distal ligature.

Mr. Bryant considered Mr. Heath's case a very good example of the Hunterian operation, but did not think the facts proved its superiority to the ligature on the distal side of the aneurism as advocated by Mr. Morris, or to laying open the aneurism and securing the vessels coming from it. The other cases raised the question of distal ligature in aortic aneurism, the results of which he had long felt to be unsatisfactory, for he quite agreed in believing that the excellent result of Mr. Heath's first case had led them to place too much reliance upon it as a curative measure. He doubted whether in most cases life was really prolonged by the procedure, although, certainly, it was made more endurable. He also thought that less risks were run, and especially the risk of increasing the blood-pressure in the sac, by tying only one vessel in preference to the simultaneous ligation of two; and he quoted two cases, in one of which he had tied

the carotid, in the other the subclavian, with relief to the patient.—Mr. Barwell hardly thought the cases related by Mr. Marsh and Mr. Morris afforded sufficient ground for debating the practice of the double distal ligation. In Mr. Marsh's case the aneurism was extending to the left, and his choice of the right vessels for ligation would favor that extension by directing the blood-pressure in that direction. Mr. Morris's deduction was hardly warranted, since in his case the single vessel he selected for ligation was actually occluded by the disease. Mr. Barwell pointed out that in cases where an aortic aneurism is pressing forwards there is always evidence of venous congestion in the left side of the neck from obstruction of the left innominate; when backwards, there are pressure signs on the right bronchus. The reason why patients were unable to reap the full benefit of the operation was because it was often impossible to enforce absolute rest, owing to the dyspnoea induced by pressure on the trachea or laryngeal nerves. But that life was prolonged by it there could be no doubt, since in one of his cases there was so much dyspnoea that the physicians declared the patient could not survive many days, and the relief given by the ligation enabled him to survive three months.—Mr. Holmes pointed out that one of the earliest cases related to the Society was almost the counterpart of Mr. Heath's case. It was one described by Sir Astley Cooper, who tied the common carotid artery for an aneurism of the external carotid. For a few days there was no appreciable effect, then pulsation ceased, and the patient was entirely relieved and passed from notice.—Mr. Heath explained that he had not deemed it necessary to refer to Sir Astley Cooper's and other cases, since this had been fully done by Mr. Morris in his paper on the subject in Vol. 64 of the Transactions.—Mr. Holmes said that such cases showed that the old Hunterian operation was adequate for the cure of such aneurisms; and certainly it was preferable to the dangerous and uncertain method of laying open the sac and tying the branches of the vessel. As to distal ligation for aortic aneurism, he had arrived at the same conclusion as Mr. Marsh and Mr. Morris had—viz., that it was best to tie one vessel first, and on all accounts the carotid is the best to select. Fearn's case was one of the most successful; and he could not agree that the clotting in the sac in that case was due to the approach of death. In many instances the formation of clot had led, if not to cure, to great amelioration. A case of aortic aneurism under the care of Dr. Ogle suddenly developed cerebral symptoms, which passed off, and the aneurismal signs forthwith disappeared. A year later the patient died of phthisis, and the common carotid was found to be occluded by clot extending from the aneurism, the cavity of which was itself reduced to a channel not larger than the normal vessels. A Canadian surgeon had published a similar case, where much the same result ensued on ligation of the carotid. Mr. Holmes had tied the left carotid in one case of aortic aneurism, and, although pulsation and bruit remained, the woman was still living, engaged in domestic service seven years after the operation. His choice of the vessel would depend upon the effect produced on the aneurism by pressure upon the vessel. He could never understand what effect ligation of the third part of the subclavian could be supposed to exert in determining clotting in an aortic or innominate aneurism, since the large branches arising from the first part remained free to the blood-current. In Mr. Barwell's case the clot in the subclavian had probably been carried from the aneurism, and had not extended backwards from the seat of ligation.

Mr. Savory pointed out that the principle of

Brasdor's operation rested on the fact that the amount of blood-pressure was in proportion to the area supplied by the blood; and therefore if one or more arteries are tied, the pressure will (after a short time) be *pro tanto* diminished. Mr. Morris's case reminded him of a possible fallacy in the practice of resorting to ligation when pressure upon a vessel diminishes the pulsation in the aneurism. He was recently called to a case of intrathoracic aneurism with a view to operation; pressure on the right carotid diminished the pulsation of the sac, but it also diminished the pulsation of the heart and of the arteries generally; and the same result followed pressure on the left carotid. He concluded therefore, that the effect was due to pressure on the vagus nerve.—Dr. Douglas Powell suggested that in Mr. Marsh's case the aneurism might have been of the form of a dilatation rather than sacculated, and inquired whether auscultation revealed that second jogging sound which he believed to be diagnostic of a saccular aneurism. Of course, if it were a dilated aneurism, distal ligation would have no effect upon it. He assured Mr. Barwell that there was no venous congestion of the left side of the neck in Mr. Morris's patient, and in his experience these venous pressure signs only occurred in very advanced cases, and pressing widely in different directions. Clinically, Mr. Morris's case seemed one particularly suitable for the distal ligation, and had it been possible to diagnose the occlusion of the carotids, he would have advised that the subclavian should be tied.—Mr. Treves, alluding to Mr. Heath's case, pointed out that the mortality after ligation of the common carotid was very high as compared with that following ligation of the external carotid, for, excluding fatalities from secondary hemorrhages, a large number die from cerebral disturbance after ligation of the former vessel. Upon distal ligation for aortic aneurism, he agreed that there were no scientific data to serve as guides in the selection of a vessel for ligation, for although Mr. Barwell had laid stress upon the direction of the blood-currents from the aorta into the right and left carotids respectively, it must be remembered that in the case of an aneurism the normal relations were much disturbed. Of thirteen cases of distal ligation in aortic aneurism, given by Wyatt, five were benefited, and six died from the operation. Mr. Treves reminded the Fellows that two years ago he had read a paper before the Society, in which ligation of the subclavian alone had cured an innominate aneurism. In that case the carotid was also tied simultaneously with the subclavian, but its ligation became detached. It must be remembered that in many cases of innominate aneurism the clavicle and sternum were eroded, and successful consolidation could not be hoped for under such conditions, the presence of the bone in the sac preventing the coagulation around it. He suggested the tentative application of a catgut ligation in these cases of aneurism at the root of the neck.—Professor Lister remarked that in his first experiment upon aseptic ligation he had applied a carbolized silk ligation to a horse's carotids, and found it to be unaltered at the end of six weeks; and a year later he had in the human subject met with a case where an abscess formed around such a ligation, a small part of which had only been absorbed. This led him to seek for a material capable of being absorbed. What was required was a material which could be securely tied in a knot, incapable of absorbing organic fluids and of itself resisting absorption. That would be the most perfect form of ligation, and had yet to be obtained. Until they had this he believed an absorbable ligation was the best.—Mr. Stanley Boyd said that the specimen he had prepared from

Mr. Heath's case showed unaltered silk fibres separated by abundant infiltration of round cells and giant cells, whereas the wound itself showed scarcely any signs of inflammation. Thus it was easy to understand how an abscess might form around the ligature.—Dr. Goodhart questioned whether any real good was attained by the medical treatment of aortic aneurism; the cases almost invariably proved fatal, and spontaneous cure was rare. Nor was clotting in the sac an evidence of cure; his pathological experience showed him that aneurisms extended notwithstanding the presence of clot, the blood being forced between the layers of clot. Therefore, he would say that an aneurism is not necessarily to be treated because it exists, and he was persuaded from post-mortem evidence that the Joliffe Tufnell treatment did no real good. He confessed himself confused as to the opinion of surgeons regarding the selection of a vessel for distal ligature, the statement of Mr. Barwell being directly contradictory to the rule laid down by Mr. Holmes in his lectures.—Dr. Broadbent, referring to Mr. Goodhart's remarks, said that the post-mortem room was hardly the place to look for cures, and could assert that he had seen very marked benefit result from the iodide of potassium treatment. Some cases he had seen seven or eight years after commencing the treatment, and he had two cases now in hospital where the signs of improvement were striking. The *modus operandi* of this treatment was much the same as that of Tufnell's plan—viz., inspissation of the blood, with the added advantage of the depressing action of the potash salt upon the heart.—Mr. Horsley briefly described the experiment of testing the comparative strength of ox aorta, kangaroo tendon, and sciatic nerve-ligatures. He also showed microscopical specimens of a catgut ligature undergoing absorption, six days after its application. The wound was quite aseptic, and leucocytes could be seen infiltrating the fibres of the ligature.—Mr. Heath, in reply, said that the object of his paper was to show that external carotid aneurism could be cured by ligature of the common trunk. Death resulted from embolism due to the cardiac disease. As to distal ligature in aortic aneurism, it might be best to tie only one artery; but Mr. Holmes had not said which carotid was to be preferred. He (Mr. Heath) had had a case of ascending aortic aneurism, in which he tied the left carotid, and the man lived for four years. If Mr. Morris in his case had tied the left carotid the patient would have died at once, for then both carotids would have been occluded. Such a mischance once happened to himself, the patient dying in a few hours after the application of the ligature to the left carotid. The cases must be very few where the vertebrals would be sufficiently large to carry on the cerebral circulation.—Mr. Marsh, in reply to Mr. Barwell, pointed out that in his case the aneurism was well towards the right, and ligature was resorted to when it showed signs of extension leftwards. He felt sure it was a saccular aneurism, but did not know if the diagnostic point mentioned by Dr. Powell had been observed.—Mr. Morris, in reply, pointed out that the consolidation of an aneurism was only a means to the end in view—the cure of the aneurism. Cure implied a shrinking of the sac, and not merely its becoming filled with clot. Suppuration and hæmorrhage may take place in the clots. Both Mr. Heath's case and that of Sir A. Cooper supported the view he (Mr. Morris) had laid down in his previous paper on the subject, that to ensure consolidation of an external carotid aneurism some of the branches of the vessel must be occluded. In Mr. Heath's case the facial and lingual arteries were found to be plugged, and in Sir A. Cooper's

consolidation did not set in until the temporal pulse could no longer be felt. In Mr. Porter's case of the Hunterian operation, suppuration of the sac seemed to have brought about the cure. The free anastomosis of the external carotid put it in a category by itself; so that treatment of its aneurism by ligature could not be compared with that of any other vessel in the body. His proposal in dealing with such cases was to ligature some of its branches, temporal, lingual, and facial, as well as the common carotid, thus protecting the aneurism from the recurrent flow of blood through those channels. Mr. Savory had raised a very interesting point—viz., whether pressure applied to the carotid artery might not reduce pulsation in an aneurism through cardiac depression from the vagus being compressed, a point which he remembered to have been stated by a writer on the subject.—The President observed that the debate showed that in spite of all the study that had been given to aneurism, the subject still admitted of much investigation.

The Society adjourned at a late hour.

MEDICAL SOCIETY OF LONDON.

Volvulus of the Ileum treated by Abdominal Section.—Abdominal Pulsation.

A MEETING of this Society was held on Jan. 15th, Mr. F. Mason, President, in the chair.

Dr. J. K. Fowler read the notes of a case of Intestinal Obstruction from Volvulus of the Ileum treated by Abdominal Section, and offered some suggestions as to the mode of performing the operation. The patient was a man, aged forty, who was admitted into the Middlesex Hospital under Dr. Fowler's care on Aug. 7th, 1882, with a history of acute obstruction of the bowels of four days' duration. An enema was administered, and by auscultation of the colon the fluid was found to pass as far as the ileo-cæcal orifice. Attention was called to this important aid to diagnosis between obstruction of the large and small intestine, and some experiments were described which tended to confirm the generally received idea that under normal circumstances the ileo-cæcal valve is competent. Abdominal section was at once performed by Mr. Hulke, and a volvulus of the ileum found and untwisted. The patient was much relieved by the operation, and the bowels were opened freely three times subsequently. Death took place three days afterwards from cardiac failure and hypostatic pneumonia. At the post-mortem examination a portion of the ileum with a long mesentery was found somewhat congested, the peritoneum generally was normal and the wound healthy. Special stress was laid upon the advisability of operating early in cases of internal strangulation of the small intestine, and attention was directed to the following mode of proceeding, at the author's suggestion, after the abdomen had been opened. The finger was passed deeply down into the pelvis, where a portion of collapsed small intestine was found; this was withdrawn and carefully followed until the obstruction was reached. It was laid down as an absolute rule that in the operation of laparotomy the distended bowel should only be manipulated in case the surgeon after a careful search had failed to find the collapsed intestine. The following advantages were claimed for this method of operation: (1) That the collapsed bowel can be examined with far greater ease and in much less time than an equal length of distended intestine; (2) that a considerable length may, if necessary, be exposed at one time, without any difficulty arising, when it is desired to return it into the ab-

domen; (3) that the collapsed intestine never leads to the duodenum—a matter of some importance; (4) that the danger from peritonitis from exposure of contracted bowel is very slight; and (5) that rupture during its manipulation is practically impossible. It was suggested for the following reasons that in all cases of obstruction of the small intestine the contracted portion would be found, as in this case, lying in the pelvis: (1) The tympanitic abdomen shows that distended bowel is on the surface, as would be expected from its diminished specific weight; (2) that in making autopsies the author had noticed that if the upper portion of the small intestine be distended, the contracted lower end is always seen lying behind the distended portion, low down in the pelvis. The explanation offered was that during the violent and continued peristalsis, and gradual distension of the bowel above the obstruction, the smaller and less active portion of bowel below is forced into the pelvis, which is, besides, too small to hold a distended loop. Two cases were mentioned which had lately been operated on at the Middlesex Hospital, in which at the autopsy a second band had been found close to one divided during the operation; the result had not in either case been influenced by these bands having escaped notice.—The President did not think a small incision in the abdominal wall a wise practice, and quoted a case of his in favor of early interference.—Mr. Bryant trusted that in future surgical aid would be invoked at an earlier period than is now customary. A volvulus was equivalent to an internal hernia, and should be subjected to the same surgical rules of early operation. Injections as a means of diagnosis would be applicable only in a small proportion of cases; and as a method of treatment, in intussusception excepted, they were of very little use. His own experience showed them to be harmful, sometimes causing rupture of bowel and fatal collapse. He nevertheless thought that Dr. Fowler's method of diagnosis in this case was ingenious and trustworthy, and in early stages might have good results. He approved the author's criticisms of the operation, and argued that the collapsed intestine should be sought for on the right side of the brim of the pelvis. He reiterated his belief in the danger of puncture of distended bowel, and had seen fecal extravasation follow puncture in three cases.

Mr. Edmund Owen compared the nature of acute internal obstruction to that kind of external hernia in which a little knuckle of small intestine was tightly strangulated; these were the very cases in which a cutting operation was urgently required. The chief signs of the acute obstruction are umbilical pain, sickness, and collapse. The co-existence of alvine evacuations was of no material import. Copious evacuations should not be employed with a view to overcoming acute obstruction.—Dr. Coupland thought that operative interference was often postponed on account of the late stage at which cases were sent into hospital. In one case of his, after operative interference had been invoked, spontaneous relief occurred before the surgeon arrived. But he would say that he had never yet seen recovery after operation in acute internal obstruction.—Dr. Green considered that the question of operation rested on diagnosis. If a physician were satisfied of obstruction in the small intestine, he would not hesitate to invoke surgical interference. Was it possible to distinguish between simple volvulus and serious obstruction.

Mr. Walsham agreed with Dr. Green on the difficulty of exact diagnosis, and the desirability of some better rule on the subject. The diagnosis between obstruction in the large and small

intestine was not quite satisfactory, and he thought Dr. Fowler's plan would prove of value. He also recommended the insertion of the hand into the rectum, which, if practiced with proper precaution, involved no risk. He thought it possible to tell the direction of the exposed intestine from noting the direction of the mesentery. He had succeeded in returning coils of intestine into the abdomen by making firm pressure with a sponge on the whole mass.—Dr. Fowler replied, and stated that it was impossible to distinguish between those cases of volvulus which would untwist spontaneously and those which would not.

Dr. Wiltshire then read a paper on Abdominal Pulsation. He pointed out that abdominal pulsation of an abnormal kind occurs in males as well as in females, but more frequently in the latter. In males it may arise from various causes, but aneurism is much more probable than in females. It very rarely occurs in girls or young women before child-bearing, and when it does usually arises from impoverished blood, but may be due to tumours, malignant or benign, or cardiac disease. It becomes more common towards the change of life and afterwards, and may then arise from various causes, which may be grouped as follows:—*Affections of the vascular system:* (1) Cardiac lesions—e.g., aortic regurgitation; (2) arterial lesions—degenerative changes, such as calcification, atheroma, etc., sometimes secondary to renal disease, aneurism, vaso-motor neuroses, peripheral spasm, pressure on the aorta, or its branches, by tumours of various kinds, fæces, abscesses, effusions; (3) blood-changes—anaemia, hydremia, chlorosis, deficiency of albumen, or various cachectic blood states arising from excessive loss or otherwise. *Extra-vascular affections:* Pulsatile tumours of the liver, spleen, stomach, omentum, mesentery, kidneys, intestinal tract or other tissues in the abdominal cavity, notably if malignant; tumours lying over the aorta, as horseshoe kidney, movable kidneys, the pancreas, purulent collections, hydatids, sarcomata, fecal collections, mesenteric cysts; neurotic affections, as from fright, anxiety, grief, shock, disappointment; Addison's disease; climacteric disorder, nervous and vascular, accompanying catamenial suppression. *Diagnosis:* Careful physical examination of abdomen, pelvis, and thorax. Inquiry into general state, particularly of blood. *Treatment:* Dependent upon cause, to discover which no effort is to be spared. Vascular sedatives generally helpful, as potassium iodide, the bromides, etc. Blood impoverishment to be amended by iron and liberal diet. Laxatives useful—e.g., an ounce of the compound decoction of aloes and five grains of iodide of potassium, three times a day.—The President had found good results from the use of laxatives.—Dr. Thorowgood had seen a remarkable case related by the author, which had been under observation for many years. He could testify to the good effect of iodide of potassium in that case.—Dr. Green had seen good effects from bromide of potassium and iron. He thought only the "neurotic" form of pulsation was unaccompanied by distinct symptoms.—Dr. Ewart had lately under his care a man, aged thirty-five, in whom abdominal pulsation of this kind occurred. The patient was dyspeptic, and had not noticed the pulsation till his medical attendant discovered it, and from that time he imagined various symptoms in connection with it.—Dr. Owen had also seen a case of the kind in a male subject.—Dr. Wiltshire briefly replied. He had seen cases illustrating all the varieties of pulsation mentioned in his paper. Many of the cases were dyspeptic and suffered from constipation. He had seen the pulsation accompany aortic incompetence and Bright's disease.

The Relation of Bacilli to Tuberculosis.

At the meeting of the above Society on Jan. 29th, Mr. F. Mason, President, in the chair, a discussion upon the relation of bacilli to tuberculosis was opened by Dr. Whipple in a paper upon a case of acute tuberculosis, complicated by albuminuria, unusually low temperature, absence of marked physical signs, consolidation of the lungs, and presence of bacilli in the sputum.

Dr. Whipple's case was that of a man, aged nineteen, who died in St. George's Hospital under his care on Nov. 14th, 1882. At the time of the patient's admission (Oct. 10th, 1882) his father was an in-patient with symptoms of phthisis. The youth had been subject to severe colds for some time, but had not been ill until six weeks previously. It appeared, however, that he had spat up some blood four years ago when he was suffering from a bad cold. Six weeks before his admission he had a slight catarrhal attack; his legs began to swell soon afterwards, and in the course of a fortnight diarrhoea set in. For two or three weeks he had been troubled by cough. There were no night sweats, and very little expectoration. He had lost much flesh of late. On admission he was suffering from dropsy. He had cough, but it was not troublesome. The lung sounds were normal. The urine contained a very large amount of albumen, and was on one or two occasions nearly solid on the application of heat. Diarrhoea was profuse. There was a little glairy expectoration. The patient made no improvement, and the diarrhoea, though perhaps it was checked for a few hours at different times, practically remained uncontrolled to the end. When the patient was first under observation no abnormal sounds were detected in the lungs, but towards the end of October slight dulness was found at the apices; a few crackling sounds were audible, which cleared up for thirty-six hours and then returned. The expectoration became rusty, and was streaked with blood. At the beginning of November there was an increase of the dulness (which was, however, not absolute) on the right side; the vocal resonance was increased, but was not louder than is often the case in persons with thin chest walls. The liver was found to be much enlarged. On Nov. 9th, a portion of the expectoration was prepared and stained by Dr. Heneage Gibbes' method, and the bacilli of tubercle were demonstrated in considerable numbers. The temperature chart, extending over thirty-two days, showed that on nineteen days the temperature was subnormal; on fourteen days only was it above 98.4° F.; that on six days only did it exceed 99° F.; and that on one evening only did it reach 100° F. The patient died on Nov. 14th, 1882; and at the post-mortem examination the lungs were extensively occupied by miliary tubercle in various stages. Tubercular ulcers were found throughout the small intestines and in the large intestine also. The liver, spleen, and kidneys were highly lardaceous. With regard to some remarkable features in the above case, Dr. Whipple pointed out:—1st. The absence of marked physical signs in a chest in which the autopsy revealed such extensive consolidation of and disease in the lungs. 2nd. The unusually low temperature which prevailed during the thirty-two days on which the patient was under observation. Dr. Theodore Williams had drawn attention to the influence of albuminuria on the temperature in cases of phthisis in a paper read before the Medical and Chirurgical Society in March, 1882, and found that when albuminuria is a concomitant of phthisis the temperature is subfebrile. 3rd. The clinical features of the case pointed to tuberculosis and lardaceous disease, yet the physical signs of

the former were, to a great extent, wanting. The fact, however, that tuberculosis of the lung frequently does not admit of stethoscopic demonstration was duly recognized, and it was suggested by Mr. F. W. Hewitt, the house-physician, that the sputa should be microscopically examined, and the discovery of bacilli constitutes not the least interesting feature in this case. Dr. Whipple then briefly reviewed the results of observations on this important subject both at home and abroad, and with regard to the method of staining had come to the conclusion that the process suggested by Dr. Heneage Gibbes was the most satisfactory. The questions which obviously occur with respect to the significance of these bacilli are:—

1. Can these organisms be demonstrated in the expectoration or other morbid secretions of persons who are, presumably, not suffering from phthisis? 2. Are they always demonstrable in cases of phthisis? and, if so, to what extent do they assist diagnosis, or indicate the progress or arrest of the disease? The results of the observations on twenty cases were then shortly stated. Of these seven were instances either of acute tuberculosis or of acute exacerbations of previously existing tuberculosis, and in all the bacilli of tubercle were found, in some cases in abundance. Four were cases of phthisis in which the disease was either arrested or was improving under treatment, and in them the bacilli were either absent or, if present, were found in small numbers. In one case sections of the walls of a vomica were carefully examined, but no bacilli could with certainty be demonstrated in the pigmented fibrous tissue bounding the cavity. Of the remainder, one was a case of rapidly fatal diphtheria in a child aged three, in which the expectorated membrane was examined, but no bacilli were found. A second was a case of acute pneumonia in an otherwise healthy man of twenty. The sputa were examined carefully on two occasions, but no bacilli were discovered. Three were cases of bronchitis, in two of which the lungs were emphysematous, and in one of which hæmoptysis occurred. In none of these were bacilli detected. One was a case of severe pemphigus in a woman aged sixty-one. The bullae were of large size; some contained clear fluid, others contained pus. Both were examined, but no bacilli were found. One was a case of undoubted tuberculosis in a casualty patient; one sputum obtained while the patient was waiting in the surgery showed no signs of bacilli. It was doubtful, however, whether the expectoration in this case came from the lungs or from the nares or pharynx. Attention was called to an important observation of Dr. Eugene Prideaux, of Wellington, to the effect that in order to obtain satisfactory results, the temperature of the magenta staining should be maintained at 100° F. Dr. Whipple's observations confirmed those of Balmer and Fraentzel, who have examined 120 cases of phthisis (*Berlin. Klin. Woch.*, 1882, No. 45), in all of which they found bacilli, while in bronchitis they found none; that the organisms are abundant in the most acute cases of phthisis, and when the disease is rapidly progressing. Professor D'Espine, of Geneva, however (*Rev. Méd. de Suisse Rom.*, Dec., 1882), only partially confirms the observations of Balmer and Fraentzel, and considers the bacilli valuable in a diagnostic point of view, but of less value in prognosis. Dr. G. A. Heron, at a meeting of Medical Officers of Health, read a paper on the results of an examination of sixty-two cases of phthisis, in all of which he found bacilli. It appears, then, that these bacilli, seeing that they are present in a very large majority of cases of phthisis, can be no mere accidental inhabitants of the sputa of phthisical patients. At

the same time due weight must be given to the statement of Professor Korgangi (*Weiner Med. Week.*, No. 51) that in a case presumably of pulmonary syphilis he found bacilli of tubercle. From Dr. Whipham's own observations, and from the published records of those of others, he was disposed to think that in acute tuberculosis and in exacerbations of the disease that the bacilli were especially numerous in the sputa, and that when the disease was arrested, or the patients were improving under treatment, the organisms were greatly reduced in number or disappeared from the expectoration. The question of contagiousness of tubercle so far has received no solution from the discovery of bacilli, and difficulties of explaining the rapid extension of diseases such as typhus or small-pox, and the comparatively slow march of phthisis, if bacilli are the sole cause of the disease, were pointed out. If the development of bacilli be the sole cause of phthisis it must be assumed that the bacilli lack the virulence which characterizes other bacteria. Otherwise there must be, as rarely happens in zymotic diseases, a large proportion of persons who present a soil unsuitable to the development of the bacilli of tubercle. The other great question of the heredity of phthisis, Dr. Whipham thought was equally inexplicable by this discovery of Koch's and that at present it is no more possible to advance any satisfactory explanation of the fact than before the discovery of bacilli. The following suggestions were made as the results of the observations which have lately been brought under the notice of the profession:—1. That bacilli may, as a rule, be found in the expectoration of persons suffering from phthisis, but that even when the disease is advanced, and rapidly extending, repeated examinations of the sputa may be required for their demonstration. 2. That they are especially abundant in the acute form of the disease, and in the exacerbation of previously existing disease. 3. That in cases where the disease is arrested, or is improving under treatment, they may be absent altogether. 4. That a solution of the questions of the contagiousness or heredity of phthisis is not afforded by the discovery of the bacillus of tubercle.—Dr. Seymour Taylor remarked on the frequency with which acute tuberculosis coexisted with entire absence of physical signs of phthisis. He believed that heredity on one side or other was common in such cases, which frequently begin with laryngeal symptoms. The low temperature might be connected with the bowel lesion, as well as with the albuminuria; for abdominal injuries in animals proved rapidly fatal from shock, and in many cases, (e.g., enteric fever) recovery from extensive bowel lesion was accompanied by subnormal temperatures. He asked whether bacilli had been found in tubercular subjects in other excretions than those of the respiratory tract.—Dr. Samuel West said that Koch's masterly investigation had left little to subsequent observers, save in confirming his results; and his own observations, which he had been making for some months, were entirely confirmatory of Koch's conclusions. 1. He had found bacilli present in every case of phthisis which he had examined, though in some cases they were in such small numbers as only to be found after repeated and very careful examination. 2. The number he had found, as a general rule, to vary with the rate of breaking down of the lung, and therefore, in most cases, with the gravity of the disease. 3. The arrangement of the bacilli in the sputum varied much. At times they were isolated, few in number or many, and very numerous in rapid cases; at other times arranged in groups and masses, and this appeared to be the rule in the most rapid cases. 4. In some instances

the bacilli contained small bright bodies, which had been called spores, and this seemed to be a common condition in acute cases. Similar minute bright bodies were often found free in these cases. It was possible they were free spores; but upon this point there were no observations forthcoming. 5. There appeared to be but little variations in the size of the individual bacilli in different cases. 6. In cavities the bacilli existed in large numbers and usually in masses. It was remarkable that they were not found in the lung-tissue to anything like the extent which would be anticipated. Two cases were referred to in which masses of extraordinary size were found in the cavities, none at all on section after section of the lung, although the characteristic chronic pathological changes of phthisis were well marked. This fact afforded the probable explanation of the variations in the number of bacilli in the sputum; the more cheesy matter or fluid from a cavity there was in the expectoration the more bacilli we might expect to find. Consequently, in a case of acute tuberculosis, before breaking down of the lung we should expect to find none; and we should further look for great and irregular variations from time to time dependent solely upon the amount of cavity-fluid discharged. Dr. West advocated caution in drawing conclusions. The presence, number, and arrangement, as well as the occurrence of spores, were all facts of some value in diagnosis, indicating the kind of process which was going on in the lung; but it was not proved yet that the bacillus was the one absolute test of phthisis. As regards the questions of treatment and of contagion, there were not yet sufficient facts upon which an opinion might be based. However tempting the theory of the contagiousness of phthisis might be in the light of these recent discoveries, clinically it was very far from being proved; indeed, clinical evidence of contagion in any ordinary sense of the term was hardly to be found. The question of the exact relation between phthisis and these bacilli could only be answered by such experiments as those which Koch had instituted; and admirable and apparently conclusive as these experiments were, they would require much confirmation before the conclusions based upon them could be unreservedly accepted.—Dr. Green dwelt on the necessity for many further observations. So far, those of different observers in the main agreed; and assuming the truth of these facts, there appeared to be no ground for separating phthisis into different varieties. Koch's experiments, if not refuted, established the fact that phthisis was a communicable disease. But bacilli were not the only agents in the causation of phthisis; if they were, all who were exposed to the contagion should become tuberculous, whereas the whole of clinical experience was against phthisis being contagious. What the other agent was had yet to be ascertained. Were bacilli the only agent in the causation it was not clear why phthisis should affect so markedly the apex of the lung. Might not that other element render the apex of the lung favorable to the growth of bacilli? And the old view that conditions which favored blood stagnation and exudation also favored the development of phthisis might still hold good. As to inheritance of phthisis, there was transmitted a general feebleness of constitution and some local weakness that laid the subject open to attacks of the disease.

Dr. Burney Yeo said that Dr. Barrow, of Liverpool, had informed him that he had detected bacilli in the urine of a case of tuberculous kidney, and in another case in the lymphatics of the lung. His own observations coincided entirely with Dr. Whipham's remarks, and he agreed with

Dr. Green as to the evidence now at hand in favor of the unity of phthisis. The absence of bacilli was as important diagnostically as their presence; as illustrated by a case under his care at King's College Hospital, which presented the characters of acute pulmonary and general tuberculosis, but no bacilli were found in the sputum after repeated examinations. The patient died, and the lesions of typhoid fever were found with the concomitant bronchitis, but no trace of tubercle. In another case of empyema communicating with the lung no bacilli were found in the pus withdrawn from the pleura, nor in that expectorated. There could be no doubt that the bacillus was one of the agents in phthisis, and as to the contagiousness of that disease, it was a subject which required investigation. He was quite surprised at the large number of affirmative replies that had been received from practitioners to the circular lately issued by the Collective Investigation Committee of the British Medical Association. Upon this question depended points of great practical importance, as in a case recently under his notice of an applicant for life insurance, three of whose sisters had died of phthisis, yet the man in question was in good health, and not one other of his relatives suffered from phthisis. The inference was that the three sisters had acquired the disease. He did not consider that the bronchi were always the channel of entrance for the bacilli, and instanced the fact of the pulmonary disease arising secondarily to intestinal tuberculosis.—Dr. Richardson hoped that the discussion would place the present position of the question plainly before the public and the profession. He thought that exact information was needed as to the way in which germs were supposed to be developed and reproduced; also as to the chemical and physical characteristics of germs and bacilli, upon which he had as yet heard little said. In an experience of over 3,000 cases of phthisis he had endeavored to arrive at conclusions respecting its mode of origin. There was, first, a well-marked peculiarity of physical organization; secondly, certain nervous and mental peculiarities; thirdly, he had found a history of exposure to cold in a large majority of cases. In one case he was in the company of the patient, and was exposed to the same chill that started in her an illness which rapidly assumed the character of phthisis and ended fatally. He showed a series of drawings of lungs from animals killed by nitrite of amyl. The earliest condition was one of striking pallor; a later state was that of intense congestion with hæmorrhages, the apices of the lungs being always affected; whilst in cases where the animals had recovered from the immediate effects, and had been killed later, actual excavation was found. These were changes not unlike those of phthisis produced by the operation of an agent which acted in a manner like a chill did upon the pulmonary vessels. He had never known any case which seemed to him to suggest the theory of contagiousness. He had known cases of phthisis attacking many members of one family, even simultaneously, but never under circumstances which supported the view of contagion. Were this doctrine true one would expect to see, in families predisposed to phthisis, frequent instances of extension from one to another. He had never seen such. He strongly held to the fact of the hereditary transmission of phthisis, and could not see how this agreed with its accidental origin by taking bacilli into the body.

At this point the debate was adjourned until Feb. 12th.

A meeting of this Society was held on February 12th, Mr. Francis Mason, President, in the chair.

Dr. C. T. Williams continued the debate on the Relation of Bacilli to Tuberculosis. (His remarks appear in another column, p. 430).—Dr. Heron said that the bacillus had now been found in many organs, and in the living subject, in the sputum, in the urine, in an ulcer of the tongue, in lupus, and in an unopened knee-joint. He had found the bacillus himself in fifty-four cases of phthisis, and he believed that practically it would always be found in cases where physical signs of phthisis existed. But in some of these cases the physical signs were so slight that he should have hesitated to make a diagnosis without the aid of the bacillus. As regards prognosis, he believed a few bacilli betokened a chronic course; a large number and persistence of them indicated a rapidly fatal course. The same results had been obtained by Balmer and Fraentzel. In rapidly sinking cases the bacilli were found in large numbers, often grouped into masses. This grouping indicated an unusually rapid course, and in one or two cases it had preceded by a day or two an aggravation of the symptoms. Some observations appeared to show that the bacilli might appear before physical signs were manifest. In some cases the bacilli, which had been present in moderate amount, had disappeared from the sputum for several weeks. In such cases he thought that the patient might be considered to be in a fair way of recovery. Heredity he had found to exist in 30 per cent. of his cases at Victoria-park Hospital during four years.—Dr. Heneage Gibbes directed attention to two points: first, the difference in the structure of miliary tubercles in the lungs and the relation of the bacilli to those of different forms; and, second, the presence of bacilli in the smallest or commencing tubercles. He showed specimens of the two forms of miliary tubercle from cases which had run a very similar clinical course, and in which the naked-eye post-mortem appearances were very similar. Microscopically the tubercles in the one specimen were of the reticular form, consisting of a distinctly fibrillated structure with one or more giant cells and a caseous mass in the centre. In the other specimen the tubercles were non-reticular, having no fibrillation, no giant cells, but consisting of irregular cells in the periphery and a caseous mass in the centre. In the one form the surrounding vesicles contained catarrhal products, in the other fibrinous exudation. He had examined a large number of lungs affected with the reticular form, and had only succeeded in finding bacilli in three cases, and these in small numbers, distributed through the reticulum. In the non-reticular form, however, he had invariably found bacilli in large numbers in the caseous centre. Dr. Gibbes also pointed out that the bacilli were to be found in the smallest tubercles. A lung may be stuffed with tubercles, each one containing thousands of bacilli, and yet the patient will die before the destructive process has gone far enough to cause any of them to be ejected with the sputum. Thus there were two forms of fatal tuberculosis in which no bacilli could be found in the sputum; and he could not agree with Dr. West that little remained to be done on the subject. On the contrary, he felt sure that the threshold of the inquiry was only reached, and that it would require long and patient investigation before the relation of the bacilli to tubercle is fully determined. He added that he had examined the lungs of guinea-pigs which had become tuberculous after being kept in the air shafts of the Brompton Hospital, and had found no bacilli in them; and he knew of an instance in which a guinea-pig inoculated with sputum from a case of phthisis presented a glandular abscess in the thigh which abounded in bacilli, whereas the external organs, although full

of tubercles, did not yield a single bacillus.—Dr. Broadbent remarked on the number of views of the pathology of tubercle and phthisis that had been in turn presented to the profession. He himself had held that phthisis was one disease, and that that disease was inflammatory. We were now looking not for a particular histological element, but for a particular irritant to start the inflammation. There were still difficulties in accepting the bacillus as the universal cause of the process. One difficulty was the fact that the disease remains for so long a period limited to one lung. The question of the communicability of phthisis was not in any way affected by the discovery of the bacillus; and he thought that the issue of a circular on this subject by the Collective Investigation Committee was an injudicious step. He believed that the replies would be largely dictated by imagination, and unless the Committee were to go behind the evidence and estimate the value of each communication, the work of the Committee would be seriously discredited. He had found better results from disinfectant inhalations in phthisis than Dr. Williams had. The bacilli were, as Dr. Gibbs had pointed out, beyond the reach of inhalations, but the cavities must contain putrid matters, which it would be an advantage to disinfect.—Dr. Drysdale said that he had repeated Villemin's experiments on inoculation of tubercle with fatal result to the animals employed; but he was not satisfied that the lesions produced were tubercle. He had for several years sought diligently for a case of transmission of the disease among his phthisical patients, but had failed to find one. In more than one-half of private patients heredity was present; but it was difficult to obtain trustworthy family histories in hospital cases. He had found no good results from antiseptic inhalations.—In reply to the President, who asked whether in the case of the guinea-pig with glandular abscess the pus containing bacilli had been taken from the interior of the gland or from the surrounding tissue, Dr. Gibbs said it was from the interior of the gland.

Dr. Whipham, in reply, pointed out that the bacilli had been found in the urine in cases of tuberculous kidney, in the spleen, and in a closed suppurating knee-joint. The undisturbed position which bacilli needed for their development seemed eminently afforded by the apices of the lungs, which might explain the selection of that part as the starting-point of phthisis. In two cases, the one related in his paper and another, the bacillus was demonstrated before physical signs appeared.

CLINICAL SOCIETY OF LONDON.

The Period of Infectiveness of Scarlet Fever.

THE ordinary meeting of the Society was held on Jan. 26th, Dr. Andrew Clark, President, occupying the chair for the first since his election. There was a numerous attendance, and the proceedings commenced by the delivery of an earnest, eloquent, and spirited address by the President, who, on the motion of Dr. Glover, seconded by Dr. Day, was formally thanked for his address and requested to have it published in the Transactions of the Society. The rest of the evening was occupied by a paper by Dr. Longhurst, which attempted to prove that scarlet fever was infective in the pre-eruptive stage, but not in the stage of desquamation. It was generally felt, however, that his facts were too few and inconclusive to warrant a deduction which, as more than one speaker emphatically pointed out, was a dangerous one to advance. An interesting case, believed by the exhibitor to be an early condition of osteitis deformans, and showing

also the remarkable state described as "spondylitis deformans," was exhibited by Dr. Lediard, of Carlisle. Cases of scleroderma were shown by Dr. S. West and Dr. Goodhart respectively. Mr. Shuter exhibited a patient upon whom he had performed subperiosteal amputation at the hip-joint.

Dr. Longhurst read a paper on the Activity of the Infective Power of the Poison of Scarlet Fever during the Pre-eruptive Stage of the Disease. He said that in a short paper on the Infection of Scarlet Fever, in *THE LANCET*, in 1877, he expressed a belief that the period of greatest activity of the fever poison was in the early stage of the disease. Extended observation has strengthened that belief, and it is borne out in the cases reported, which seem to encourage a line of investigation in connection with the study of acute specific diseases advocated by the late Dr. Murchison in a paper on the Period of Incubation of Scarlet Fever and the probability that they may be transmitted even during the stage of incubation. Case 1 supports such view, and forcibly demonstrates that the fever poison is not absorbed by, nor developed in, all persons with the same rapidity and activity, and that possibly even during the stage of incubation the poison may be passed on from one member of a family to another, the latest case having little, if any, direct relation to the first, but being due to the further development of the poison through fresh systems. Cases 2, 3, and 4 all point to the activity of the fever poison in the very earliest stage, whilst Case 4 is especially interesting as proving that the long isolation and confinement still enforced by some are not always necessary. It is most important that a belief in the activity of the infective power of the fever poison during the very earliest stage, possibly also during that of incubation, should be generally accepted; for then, instead of risking the spread of the disease by scattering at once the members of a family, forming new and fresh centres of infection, ought we not rather to be content with isolating the sufferer in his own house, or removal to the hospital, according to circumstances, and with rigidly adopting all sanitary precautions? If also we admit the activity of the fever poison to be in the earliest stage rather than during the stage of desquamation, as still held by some, then we could feel that the long period of isolation and confinement of two or three months, as still in the opinion of many is deemed necessary, may be safely shortened, to the very great relief of both the sufferer and his family.—Dr. Broadbent said that before evidence of this kind could be accepted of the contagious power of the fever in the pre-eruptive stage, there must be proof that the other children were not exposed to the same source of infection as the first was; but amongst a number of children this exposure to the same source of contagion was very likely to occur. Until we have cases occurring alone, and exposed only to a case in the pre-eruptive stage, the point could not be proved. His own experience was that even where two children slept in the same bed until the eruption came out on one of them the other might escape, and that some children were more susceptible to the poison than others. It was different with regard to measles, which, he had no doubt, could be communicated in the preliminary catarrhal stage. He had seen both in measles and mumps children sent away from a house where these diseases occurred going to a family at a distance and communicating the disease, although they did not present the symptoms until after their arrival. No such exposure in the early stage of scarlet fever sufficed to transmit the disease. He would agree with the author as to the danger of sending away other children as soon as one case occurred. At

the Fever Hospital, although every possible precaution is taken to disinfect the clothing and persons of children on being sent home, even at long intervals of six or eight weeks, others have been infected.—Dr. B. O'Connor remarked that it would have been interesting if the infection in the cases related had been traced to some articles of diet, as happened in the Kensington epidemic a few years ago.—Dr. Gilbert Smith said an important detail is the length of the period of incubation. In an orphanage with which he was acquainted a child returned from a stay in London, and next day had a scarlet fever rash. The same nurse attended to the other children, who next day had sore-throat, showing that incubation in these cases occurred within twenty-four hours. Dr. Smith, of the Fever Hospital, had informed him that if the disease had not appeared within seventy-five hours of exposure it would as a rule not appear at all.—Dr. Glover thought the Society should by no means accept the conclusions of the author, because of their grave public importance. Isolation of cases was a common rule, and anything tending to destroy faith in it would be disastrous, for in the later stages scarlet fever is very seriously infectious. At this very time the author of the paper would send patients away to communicate the disease far and wide.—Mr. Jessett said that the most important part of the paper was the very early stage at which the author sent patients out of town. It was far too soon to send them away at the end of three weeks. During the stage of peeling the disease is the most infectious. He mentioned a case where contagion occurred through a patient going to a calico ball, thirty or forty people being infected. He could confirm what had been said by Dr. Broadbent as to the infectiousness of measles in the catarrhal stage.—Dr. Eastes said that in 1866 he had scarlet fever, and a brother came to see him and contracted the disease, returning to school, where fourteen other boys slept in the same dormitory. The rash appeared next day, and he was isolated. Not one of the other boys took it. At a school in the country a child was taken ill with others, and all precautions were observed. At the end of six weeks she went home, and the other children in her house became ill.—Dr. Black gave an instance of infection of measles in the catarrhal stage. A pupil of his one day was suffering from severe catarrh, and next day presented the rash of measles. A short time after (fourteen days) his own two children developed measles, apparently from his having himself conveyed the disease from his pupil.—Dr. Duckworth said there was much misunderstanding as to the period at which scarlet fever cases should be sent away, and a rule was required which should be applicable in all cases. His own plan was that the patient should be kept under the blanket for at least three weeks, and confined to his room for eight or ten days later; and if this were inflexibly carried out we should hear very little of renal complications and other troubles. It was a sound, practical, working rule, which should be enforced even in the mildest cases.—The President said there was no question of the importance of the subject. The writer had not proved his position, for he had failed to show that the children were not exposed to the action of the same poison. As to the time at which a patient should be removed, he held there was no reasonable safety within six weeks; no perfect safety within seven. Some years ago he had scarlet fever in his own house and was called to Scotland. He declined to go, but the idea of any risk was ridiculed, and he was again urgently summoned. He waited for six weeks and went, when, within a week of his arrival, scarlet fever broke out in the place.—Dr. Longhurst, in reply, said he had ex-

pected severe criticism. He admitted that he had been unable satisfactorily to trace the source of infection in the cases, and that all might have been infected from the same source; but as all occurred within a week, it proved that there is infectivity in an early period of the disease; and his main contention was, that infection is during the early stage rather than in the stage of desquamation. In estimating the probable period of incubation, one was apt to be misled by infection from clothes and surroundings.

Subperiosteal Amputation of the Hip.—Nephro-Lithotomy.—Urinary Test Pellets and Papers.

The ordinary meeting of this Society was held on Friday, February 9th, Dr. Andrew Clark, President, in the chair. There was a large attendance of members, and the communications read all excited much interest. Although there was doubt expressed by some as to the presence of new-formed bone in the stump of Mr. Shuter's patient, all agreed that the result obtained by the amputation was remarkably good. So far as mere operative surgery is concerned, the successful removal of the enormous stone from the kidney, shown by Mr. Bennett May, may certainly be called a triumph of surgery, such as could hardly have been anticipated by the earlier operators upon the kidney. Not less interesting than these two striking cases were the demonstrations in urinary testing by Drs. Pavy and Oliver, and while both methods were obviously practical and admirable, it was evident that Dr. Oliver's tiny test papers were more quickly used than Dr. Pavy's pellets, and equally accurate.

Mr. Shuter read a paper on Subperiosteal Amputation at the Hip-joint. On Oct. 16th, 1881, the author had a consultation with Dr. Samuel West and Mr. Rose on a male patient aged eighteen, in whom he diagnosed acute necrosis without suppuration in the lower end of the left femur. This had led to septicæmia and secondary inflammation of the left hip-joint. Although the diagnosis was not supported, it was agreed that nothing but amputation at the hip-joint would save the boy's life. The next day the following operation was performed. A circular amputation through the junction of the middle and upper third was done, followed by a longitudinal incision on the outer side of the femur down to the bone, the periosteum stripped off and left in the flaps, and the whole of the bone enucleated. The patient made a good and rapid recovery. A little more than two months after the operation he had a movable stump, and within six months of the operation he was wearing an artificial limb, on which he could get about very satisfactorily, and continued to do so until a few weeks ago, when the use of this was discontinued in order to allow a sinus to heal. In 1859 Professor Ollier, of Lyon, after performing many experiments on the lower animals, devised subperiosteal operations on the human subject with the view of obtaining bony support to flaps cut for disarticulations. Among his suggestions was an operation similar to the one Mr. Shuter performed on the hip-joint. This case, however, is the first successful periosteal amputation at the hip-joint which has been attended with the formation of bone in the stump, and in which the patient has been able to wear an artificial limb satisfactorily.—Mr. Bryant congratulated Mr. Shuter on the success of his case. The stump was certainly good and very firm. He differed from Mr. Shuter, however, as to there being bone in any quantity present. There might be microscopical portions of bone, but practically he thought there was none. The leaving of the periosteum gave the muscles a

firm attachment. The operation was first cousin to, if not identical with, the operation suggested by Mr. Furneaux Jordan. In many cases, he thought, the periosteum could be preserved, but in others it could not. In such a case as Mr. Shuter's it was easy to separate the periosteum, as the bone was inflamed. But in many cases needing amputation at the hip-joint for tumour it would be impossible to separate the periosteum. Mr. Shuter's stump was, he must say, the best result he had ever witnessed after this amputation.—Mr. Croft said that this case was comparable to a complete excision of the hip-joint subperiosteally, which had been said to be impossible. He asked Mr. Shuter how he peeled the periosteum from the great trochanter, which at this age was ossified to the shaft. It was evidently most desirable to save the periosteum in amputation at the hip-joint where possible. He thought there was some bone in the stump, making the stump a very good one.—Mr. Barker referred to a precisely similar operation published by himself last month in the *British Medical Journal*, in which the result was exactly the same. The operation was performed in February, 1881, and the patient had an excellent firm movable stump with a solid axis of bone. In this case the exarticulations of the bone was done subsequently to the division of the soft parts. The disease was suppurative of the hip-joint.—Mr. Cripps thought there was no new bone produced in the stump. Twice lately he had assisted at amputation of the hip-joint by Mr. F. Jordan's method; but it seemed to him to prolong the operation very greatly, and so to detract from the safety of it. Mr. Jordan recommended his method because of the ease of controlling hæmorrhage, but the introduction of Davy's lever had lessened the value of this argument. The value of rapidity in this operation was certainly great.—Mr. Pick said that, anyhow, Mr. Shuter's patient could wear an artificial limb, which was a matter of the gravest importance. He had lately attempted, unsuccessfully, to invent an artificial limb for a case of amputation by the old method, which left the patient very painfully mutilated and forced to go about with crutches only. No artificial limb had yet been devised for these stumps, and Mr. Shuter's result was, therefore, a very gratifying one.—Mr. Howard Marsh proposed that the case be referred to a committee, with a view of determining whether there be any new bone in the stump, and the way in which the man used the artificial limb, whether he moved it at the hip or only from the spine. He had seen Mr. Davy's lever used many times, and it had always been efficient, and so he thought the prime object of Mr. F. Jordan's operation was attained by it, but he had performed it twice, and found it much more tedious than the flap method.—Mr. Butlin thought that it was impossible to amputate subperiosteally by the flap method. He certainly believed there was bone in this stump, which was a much better one than was usually seen after this amputation.—Mr. Barker said that in his case there was no bone left behind at the time of the amputation.—Mr. R. Davy thought the subperiosteal method caused less injury to the deep structures of the limb than any other. At the Surgical Aid Society they had been quite unable to devise any artificial limb which could be usefully adapted to the stumps left after hip amputations. He now had to record a misfortune in the use of his lever. It occurred at the Westminster Hospital in an amputation of the right hip in a man aged forty. He himself applied the lever, and noticed nothing untoward at the time. That evening peritonitis came on, and next day the patient died from peritonitis; at the autopsy a small linear rent was found in the

rectum. He had used the lever himself eighteen times, three times since this accident, and had not lost his confidence in it. Altogether he knew of forty cases in which it had been used, twenty on the right side, and in these cases there had been 65 per cent. of recoveries. The case recorded was the thirtieth. The lever was used with all care, and the accident was caused by shortness of the meso-rectum, which was demonstrated after death. He had been present at seven autopsies after the use of the lever, and in no other than the one recorded had there been any evidence of injury to the rectum.

At the President's suggestion Mr. Shuter's patient was here brought into the room with his artificial limb on, and he walked round quite firmly and easily, demonstrating that he could not only wear, but use, the limb. The man stated that he could walk some distance with it.—Mr. Morrant Baker had had three successful cases of amputation at the hip-joint, but in neither was the stump so good as in Mr. Shuter's. He attributed this result to the very long skin flaps, rather than to the subperiosteal method employed. He thought there was actually bone in the stump, but that it was of secondary importance.—Mr. Morris believed that the man walked with motion between the stump and the pelvis. He thought that the subperiosteal method did not add to the difficulty of the operation. Only two days ago he had operated on a boy with disease of the upper end of the shaft and of the femur, and he quite readily separated the thickened periosteum from the bone.—Mr. Clement Lucas thought the case was of sufficient importance to be referred to a committee. In his opinion the bone in the stump was very small in amount, if present at all, and he thought that the excellence of the stump was rather due to the stripping off of the muscles in their normal connection with the periosteum.—Mr. Shuter stated that since his case he had assisted at a similar operation, where three months afterwards the man died, and in that instance a mass of bone was actually found in the stump after death; he therefore came to the conclusion that there was ground for asserting that there was bone in his own stump. The operation was really devised by Ollier in 1859, and not originally by F. Jordan. In his case he did not remove the periosteum from the great trochanter. In the case he assisted at afterwards, of a man aged thirty, the periosteum was removed from the trochanter without much difficulty; the only difficulty was in starting the stripping of the periosteum. He thought the man could move his artificial limb forwards or backwards by the stump itself.—Dr. A. Clark said that in the discussion three questions had been raised:—(1) as to the structure of the stump; (2) as to the mobility of the stump; (3) as to the relative value of the three methods. He nominated Mr. H. Marsh, Mr. Clement Lucas, and Mr. Croft as a committee to investigate these questions and report to the Society.

Mr. Bennett May (Birmingham) showed a patient from whom he had removed a large Stone from the Left Kidney (calculus shown). The case closely resembles that of Mr. Henry Morris, which was the first of the kind, and was communicated to that Society in November, 1880; as also the subsequent cases by other operators, all of which had been discussed there. It showed an advance in point of size and weight of stone removed, this being three inches long and an ounce in weight. The patient, a coal-miner, thirty-four years of age, had his first symptoms of the disease when sixteen, in the form of severe and characteristic pain in the left loin, which, after recurring several times during the next few years, completely left

him till twelve months ago. During the interval, blood constantly appeared in the urine after exertion, and this, together with a permanent, ropy sediment, left no doubt that a stone was present in the kidney all the time, and slowly growing there. In November, 1881, pain returned with great severity after a hard day's work, and since then he could only live in comfort by avoiding every exertion. A fast walk, rough work, or drive in a conveyance brought on an attack of renal colic, which, beginning with rigor and sickness, was attended with severe pain in left loin, radiating down the course of the ureter into the testis and thigh, and after lasting six or seven hours was followed by copious hæmaturia and frequent micturition for the next day or two. There was frequent turbidity of the urine from pus and phosphates; but the amount was subject to frequent aggravation. The existence of a stone in the kidney was diagnosed by his medical attendant, Dr. Hartill, of Willenhall, at whose instigation he came to Queen's Hospital for an operation. While here, an examination of the loin and abdomen showed complete absence of any tumour or difference on the two sides, or tenderness on pressure and palpation; but the act of stooping was a source of great local pain. He seemed in fair health, but expressed his life as being unbearable, owing to the impossibility of earning his living. His symptoms, with the exception of slight turbidity of urine, being nearly all in abeyance, he was got to do some fast walking, which brought on one of his attacks, and on the following day he voided, *per vias naturales*, a small calculus, too small, however, to be regarded as the source of his troubles, or the growth of eighteen years. The operation was performed October 20th, 1882. The finger failed to make out a stone, but acupuncture detected it at once. The kidney substance was incised in a vertical direction until the wound appeared large enough to permit the extraction of the stone, which was accomplished by a scooping action of the forefingers and gentle traction on its smaller end. Bleeding of a venous character was profuse, but controlled by pressure. The parenchyma of the kidney appeared healthy; there was no appearance of pus or a thickened sac, and the cavity, after removal, was felt to be free from fragments. For the first twenty-four hours there was intense pain and some shock, and the urine contained much blood. On the following day urine began to flow through the lumbar wound, but it ceased entirely on the twenty-first day. The wound healed by the fifth week, never showing any tendency to the formation of a urinary fistula. At the beginning of the second week there was a slight attack of pleurisy with effusion on the same side, not septic, probably diaphragmatic, and due to contiguity of tissue. He had quite recovered from it at the end of another week. The urine had slowly returned to a nearly normal standard; blood-staining disappeared after four or five days. The latest report (Jan. 31st) is that it is still opalescent and turbid, with small quantity of pus and phosphates. He had tested his recovery by active exercise and numerous rides by rail. He feels perfectly restored to health, and free from pain, and fit for active work. The diagnosis was not very difficult to establish, the symptoms being sufficiently distinct from those of stone in the bladder. The only embarrassment resulted from his voiding a stone two days prior to operation, but the patient himself experienced no relief in consequence. It was found convenient, during the operation, to divide the edges of both erector and quadratus muscles. The kidney fell forwards, and by its recession when touched increased the depth of the wound to something considerable; and it was perhaps owing to this cause

that the stone could not be palpated. The fingers, retained in the wound of the kidney whilst being made and during extraction of the stone, acted as a plug, and arrested bleeding, which would otherwise have been very profuse. The principal feature of interest was the question of completeness of ultimate recovery, and of restoration of the kidney as a healthy working organ, after the infliction of such severe injury by the presence of so large a stone and by the operation. From the state of the urine for a long time there must have been some degree of pyelitis, but there was no visible destructive change at the time of operation, and to that fact, which has been pointed out in the discussions of this Society, his recovery, was no doubt due. The stone appeared to consist largely of a crystalline phosphate of lime, but it probably contained one or more nuclei of oxalate.

Mr. Howse had performed this operation ten days ago on a case different from Mr. May's. The stone weighed twenty-six grains, consisting of oxalate of lime. The patient was a sailor, aged fifty-six. Six years ago he had sudden severe pain in the right loin, passing down into the thigh, accompanied by vomiting. The pain suddenly subsided, and next day he passed sand. About every seven months he had had another similar attack up to two years ago, when the pain became constant, and since then he had not passed any sand. He complained of continual forcing pain in the right loin and a feeling of needles running into his right kidney. The pain did not run down into the thigh. There was a tender spot in the right loin. The urine was free from crystals; no blood, mucus, or albumen. Mr. Howse cut down on the kidney, making a transverse and vertical incision. The finger felt the front of the kidney, also a small stone; behind he could not feel it, and it was therefore important in all such cases to examine the kidney from the front, with the organ firmly supported by the psoas. He found the lower end of the kidney, grasped the calculus with his finger and thumb, tore the kidney with a director, and extracted the stone. The temperature had once since risen to 102°, but was then 99°. The man was doing well; the urine was draining freely from the wound, but was quite sweet.—Mr. Clement Lucas remarked that hitherto the cases published had been those of small stones with healthy kidneys, and of large stones with destruction of kidney. The real distinction was to be made between cases of stone in healthy kidney and stone of any size in degenerate kidney. He thought it very important in these cases to explore the kidney from the front against the resisting psoas muscle.—Mr. Butlin said that the stone removed by Mr. Bennett May was enormously larger than any other yet recorded. He had recently heard from his patient whose case he recorded before the Clinical Society last year, and he was quite well; he had had an attack of gravel, in which the symptoms all pointed to the affection of the other kidney. He could not agree with Mr. Barwell in thinking that in all these cases the kidneys should be excised as being diseased organs; this should only be done where the organ was obviously disintegrated.—Mr. Morris asked Mr. Howse whether he would advise his operation in all cases in which he had to cut down upon the kidney for exploration. He thought it added greatly to the difficulty and danger of the operation, and that if the loin were well propped up, and the kidney supported by an assistant, the kidney did not fall forwards away from the hand. In two cases he had recently explored a kidney, and had not found a stone. After these operations, and a similar one since that he had seen, recovery followed without any difficulty, and in one

of them, at any rate, benefit followed. He suggested that this improvement might be due to the cicatrization of the wound giving the kidney greater fixation than before.—Mr Bennett May thought that it still remained to be ascertained whether the kidney in these cases completely recovered and became a useful organ. In his case it would have been hardly possible to explore the front of the kidney, as the wound was so deep. Abdominal pressure did not fix the kidney, as Mr. Morris had suggested.

Dr. Pavy demonstrated a Test for Albumen in the Urine, by the use of Ferrocyanide Pellets. The convenience of the cupric test pellets for sugar had convinced him that it would be very desirable to have similar pellets for detecting albuminuria. Metaphosphoric acid was a good test for albumen, but he failed to get a satisfactory pellet. Ferrocyanide of potassium and acetic acid had been long known as one of the very best tests for albumen. He had replaced acetic acid by citric acid, which acted as well, and the potash by the sodic ferrocyanide. The pellets were made of citric acid and sodic ferrocyanide only. For use the pellet must be crushed, dropped into a test-tube, and the urine poured in to the height of one inch, and shaken, and if albumen be present a precipitate is at once formed, and by allowing it to subside its quantity could be measured. It acts equally well in alkaline and acid urine, and phosphates do not interfere with it. Urates must be redissolved by warming the urine before adding the pellet. If a pellet were dissolved in a small quantity of water, and urine carefully poured down the side of the test-tube on to the solution, a ring of precipitate appeared at the line of junction of the two fluids if albumen were present, and on agitation and mixing the fluids this precipitate was increased.

Dr. Oliver (Harrogate) showed his Test-papers recently described in our columns; he had six specimens of healthy urine, and six specimens of urine containing from .75 to 1 per cent. of albumen; by simply dropping the papers into the twelve tubes, the latter six were at once distinguished by the formation of a white cloud, or a white flaky precipitate. He stated that he had also devised test-papers for the detection of sugar.

Two cases of Pseudo-hypertrophic Paralysis affecting two adults (brothers) were shown by Dr. J. K. Fowler. Also a case of Fracture of both Bones of the Forearm, in which Mr. Godlee had excised the lower end of the ulna.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on Jan. 11th, 1883, Mr. B. Walker, President, in the chair.

Excision of Wrist.—The Pathological Committee presented its report on the specimen exhibited by Mr. Favell at the meeting on Dec. 7th. Amputation had been performed in the lower part of the forearm in a case in which excision of the wrist had some time previously been done. The report described the dissection of the specimen, which revealed caries of the metacarpal bones of the index and middle fingers and of the lower end of the radius. The flexor tendons of the wrist were somewhat matted to the surrounding structures, whilst the extensor tendons, some of which had evidently sloughed away, were still more firmly fixed.

Intussusception.—Dr. Sinclair White related the particulars of this case. The patient, a boy, aged five, was admitted into the Public Hospital, on Dec. 14th last, with most severe scalds of the buttocks and thighs. There was also slight bronchitis. There was no collapse, and the child was

comfortable through the night and next day until 5.30 P.M., when vomiting and purging commenced. This continued, and he became collapsed and died at 7.30 the same evening. The post-mortem showed an intussusception of the small intestine at the junction of the jejunum and ileum two inches long. There were no inflammatory signs observed, and a full-sized catheter could be passed through the invaginated portion. Dr. White suggested as queries, Was the intussusception the cause or the result of the vomiting? or, Was it produced about the time of death?

Sarcoma of Femur.—Mr. R. J. Pye-Smith showed the knee, etc., which he had amputated the day before on account of a tumour about the internal condyle. A. H.—, a lad, aged nineteen, had had slight pain in the right knee for three or four months, and for six weeks the inner side of the knee had been enlarging. He had kept at work as a glass-moulder, which involved his kneeling constantly, till he came to the Sheffield Public Hospital and Dispensary three days ago. There was a firm, smooth, tumour, as large as a fist, growing apparently from the inner condyle. It was slightly tender, but not red, and it did not pulsate. The inguinal glands were not enlarged. On admission an exploratory incision was made, and some small pieces of a soft, tumour mixed with bone were removed for examination. They consisted of very variously shaped large cells, without any well defined arrangement. The limb was amputated next day in the middle of the thigh. On making a section of the tumour, together with the femur, the lower end of the shaft was found to be slightly enlarged, and infiltrated with a soft, pale material, which invaded to a small extent the epiphysis also. The inner wall of the bone was replaced by a blood-stained growth, nearly as large as an adult fist, made up of a loose, bony framework, containing small nodules of soft brainlike tissue; it was not encapsuled. It seemed evidently a malignant growth, corresponding with cases formerly described as encephaloid, but classed as sarcomatous by more modern authorities. The specimen was referred to the Pathological Committee for examination.

Case of Pericarditis with Effusion.—In brining forward this case, Dr. Martin referred to the insidious onset of the disease, and to the fact that it had only been preceded by rheumatic shoulder pains, so trivial as to escape the patient's attention. There was no further personal history of rheumatism, nor, indeed, any in the family history. The patient, aged twenty-nine, formerly a wine and spirit merchant, was a well nourished and well developed man. He had taken freely of alcoholic drinks. Dr. Martin had first been consulted on January 5th this year. The patient had just changed houses in consequence of the dampness of the one he had left. For some time he had experienced a cough and dyspnoea, and for ten days before the date mentioned he had not been able to lie down, and had suffered from sleeplessness. Now the heart's dulness was found greatly enlarged, being five inches and a half vertical by six inches horizontal; no displacement of point of impulse. A double friction murmur was heard at the heart's apex, and well round into the axilla. There was no elevation of temperature; the treatment adopted consisted in the application of a blister and the administration of digitalis with the iodide and bicarbonate of potassium. Recovery was rapid. On January 11th the dulness over the heart had receded to three inches in the vertical and four inches and a half in the horizontal direction. Friction sounds were diminished. Dr. Martin laid great stress on the point that we may have inflammatory affection of the great serous.

membranes, which must be regarded as a local manifestation of the gouty or rheumatic dyscrasia and not as idiopathic disease. An interesting discussion took place connected with the points raised and as to the benefit to be derived from blisters, in which the President, Drs. Law, Dyson, Gwynne, and Davies, and Mr. Pye-Smith joined.

A meeting of this Society was held on Jan. 25th, 1883, Mr. B. Walker, President, in the chair.

Mr. R. J. Pye-Smith related notes of a case of Injury to the Knee, with Rupture of both Crucial Ligaments. G. W., a cabman, aged fifty-three, was admitted to the Sheffield Public Hospital on Dec. 25th, 1882, having twisted his right knee in falling from his cab. There was considerable lateral mobility of the joint and it contained some fluid. Pressure was applied by means of an elastic bandage over cotton-wool, and the swelling subsided, leaving extensive ecchymosis. Pneumonia soon developed at the right apex (the patient had been drinking heavily for six months past), and was fatal on the eighth day after the injury. Post mortem the internal lateral ligament and both crucial ligaments were found to be completely ruptured, the latter close to their femoral attachments. The central part of the cartilage of the patella was crushed into fibres, so as to present a plush-like appearance. The joint contained a few small clots of blood. The injuries to the ligament seemed to point to forced eversion of the leg at the knee as their most probable cause. Extreme rotation of the leg inwards might possibly have produced them. There was no dislocation of the joint nor injury to the popliteal vessels. The upper lobe of the right lung was in a state of red and grey hepatization.

Mr. G. S. Taylor related the particulars of a case of Malignant Polypus of Uterus. The patient, aged sixty-four, had been under treatment for nine years for attacks of profuse uterine hæmorrhage, which lasted for a few days or few weeks, and she died three days after the last attack. She menstruated at eleven years, married early, and had three children, the last forty years ago. There was always a great loss at menstrual periods, and no climacteric cessation. No pain was experienced, and the discharges between the hæmorrhages were never offensive and mostly watery. Attempts to explore the uterus brought on excessive bleeding. No growth ever descended through the canal of the cervix. After death the abdomen was opened and the uterus examined; it was five inches and a half long; outer surface smooth, presenting several cushioned projections; the os soft and patulous. The cavity was occupied almost entirely by a mass somewhat like placenta, and showing large vessels attached to the fundus and bathed in soft medullary matter. The uterine walls were considerably thickened from infiltration which in places formed nodules. Both ovaries were firm white masses, each the size of a pigeon's egg. Under the microscope sections of the growth, the walls of the uterus, and the ovaries exhibited the characters of medullary carcinoma. Mr. Taylor considered this to be one of those rare cases mentioned by West, Simpson, and a few other writers, in which a polypus of malignant structure grows from the interior of the uterus independent of previous disease of its orifice. The points of interest were the almost total absence of pain, the character of the discharge, and the long continuance of the disease.

Dr. Martin read a paper on Questions as to the Nature of Fever Poisons. Having reviewed some of the older theories as to the nature of the infective matter, he went into the germ theory, and broached the view that the phenomena of fever, be

the special form what it may, are not produced by the mere presence of germs as germs, but that they are due to the presence of some toxic product, dependent upon the existence, growth, and waste of different species of germs in the systems of the patients affected. This product may be an excretion, or possibly a secretion, excreted or secreted by the germ. What its clinical nature may be Dr. Martin does not profess to know; possibly it may be alkaloidal in its constitution. He drew attention to Pasteur's experiments with the chicken cholera bacterium, when, with the fluid freed by careful filtration from the presence of germs, he obtained by inoculation toxic and narcotic effects similar to those observed in the disease itself. Dr. Martin disagreed with M. Pasteur's conclusion, that because the effects were only slight and transient, therefore it could not be said that the disease was due to a poisonous product apart from the germs themselves. The toxic product, whatever it is, could not propagate itself and was soon cast out; but when the germ is living and multiplying there is a constantly increasing supply. Dr. Martin pointed out a fact that had come to his knowledge after his paper had been written, that Pettinkofer foreshadowed this view in connection with the subject of cholera.

At the meeting held on Feb. 8th, 1883, Mr. B. Walker, President, in the chair, the Pathological Committee presented its report on Mr. Pye-Smith's specimen of tumour of femur, exhibited at the meeting on Jan. 11th. The opinion expressed was that the growth was sarcomatous; it consisted mainly of cells, varying a good deal in shape and size, but in most parts corresponding pretty much with those of a large round-celled sarcoma, together with a well-marked stroma of homogeneous structure surrounding most of the individual cells.

Mr. Walker related the particulars of a case in which a silver plate with two artificial teeth attached passed per rectum. The patient, a woman aged forty-two, applied at the Rotherham Hospital on July 22d last, stating she had swallowed her false teeth and that they were sticking in her throat. On examination, however, with the finger they could not be felt. On July 26th the plate and teeth attached were passed per anum. Mr. Walker exhibited the plate; it measured across about seven-eighths of an inch, and on either side was a fine hook.

Mr. Snell exhibited photographs, and gave particulars, of a case of Extensive Scarring of an Infant's Face from Injuries at the time of Birth. The child had been brought to him at the General Infirmary last summer, when it would be about three or four months old, as the mother wished to know if the condition of the eyes could be improved. There was ectropion of both upper eyelids, especially the left, which exposed a good deal of conjunctiva. In addition to this, however, the forehead was seamed almost all over with cicatrices, which also ran over the nose, the point of the latter being puckered in, etc. On the left cheek was a large semicircular scar running from the nose to the mouth, but the right cheek was the most affected, and the right auricle seemed in a great measure destroyed and tied down by the surrounding cicatrix. The surface of the head was scarred also, and the condition here and in other parts was described in detail. The only explanation offered for this condition was that given to Mr. Snell by the medical man who, called in at the confinement, had arrived late, and found a midwife industriously rubbing with a towel the face and head of the baby. He desired her to de-

sist, but to this he attributed the child's condition. Doubts were expressed by several gentlemen as to the sufficiency of this explanation.

Dr. Dyson showed the morbid specimens from a case of Mediastinal Tumour. The patient, a woman aged thirty-two, the mother of five children, had been under his care in the Sheffield Public Hospital. She stated she had been ill nine months, and attributed her illness to hurrying along the street once with a heavy child on her right arm. The tumour occupied the mediastinum, and had invaded the whole of the right lung, the left lung being unaffected. The superior vena cava and right phrenic nerves were completely surrounded, the former being only slightly patent. The new growth had also invaded the auricles, and, proceeding down the right side of the pericardium, had exerted considerable pressure on the inferior vena cava. This last circumstance explained the oedema of the lower extremities, and the immense distension and enlargement of the superficial veins on the abdomen. The growth had the appearance (microscopic and naked eye) of a lympho-sarcoma. Growths of a similar nature were found in the substance and in the surface of both kidneys, in the right ovary, and in one or two places subcutaneously. On the surface of the kidney and in the right ovary, the growths were caseating, and converted into greenish puruloid fluid. The symptoms were of the usual varied and distressing character, and the whole period of illness barely lasted a year.

Dr. Porter read a paper on Lead Palsy, in which, after referring to the prevalence of cases of lead poisoning in Sheffield owing to the use of a lead cushion in file cutting, the lead bath in file hardening, and the lead-coated wheel or "lap" in penknife finishing, he quoted from some statistics he had taken from the patients suffering from this disease at the Sheffield General Infirmary. Twenty-five out of thirty cases which he noted had occurred among file-cutters, and he drew attention to the fact that in this trade the advent of symptoms was generally delayed; thus, in sixteen cases the average time between the first exposure to the poison and the first appearance of symptoms was fourteen years; in eight more the actual time was not noted, and in one case only did they appear directly after exposure. But although their appearance might be delayed for years, or they might be absent from first to last, the usual indications of general ill health which precede them were very seldom wanting, and many of these file-cutters who had never presented any of the symptoms peculiar to lead poisoning carried the indications of their trade in the unhealthy, cachectic appearance of their faces and the blue line on their gums. Referring to the relative frequency of the special symptoms of lead poisoning, Dr. Porter stated that in the thirty cases before referred to colic had occurred in twenty-seven, some loss of muscular power or paralysis in eighteen, and eclampsia in two. The characteristic blue line was present in twenty, and of the other ten cases six had not been working among lead for some time, and in three more the fact of its presence or absence was not noted. Speaking of lead palsy, he believed that when that was the only symptom of lead disease it occurred usually only after long-continued exposure to the poison; as in three such cases which came under his observation, one was after eighteen years, another after twenty-two years, and the third after thirty years' file cutting. Referring to the pathology of lead palsy, Dr. Porter alluded to the experiments and researches of Vulpian and Charcot, and stated that it was still a disputed point whether the paralysis was due to an anterior poliomyelitis, or affection of the ganglia of the

anterior cornua of the cord, or whether it was to be regarded as the result of a general peripheral neuritis, independent of spinal lesion. In conclusion, he dwelt particularly on the importance of preventive measures being adopted among those who were unavoidably exposed to the action of lead.

ACADEMY OF MEDICINE IN IRELAND.

PATHOLOGICAL SECTION.

A MEETING of the Pathological Section of the Academy of Medicine in Ireland was held in the Albert-hall, Royal College of Surgeons, on Friday evening, January 5th.

Specimens Exhibited by Card.

Dr. F. Henston exhibited an Oval Dermoid Tumour of the Right Ovary, the circumference being ten inches and the diameter nine. He had removed it from the body of a dissecting-room subject, aged sixty-five. The tumour was connected by adhesions with the surrounding viscera. Microscopic sections of the wall of the cyst showed bony plates and nodules of cartilage. A fibroma existed in the upper and posterior portion of the vagina.

Mr. Arthur Benson exhibited drawings of two cases of Rupture of the Choroid from External Injury. Case 1: From the left eye of a man, aged thirty-three, who received the injury three weeks before admission into St. Mark's Ophthalmic Hospital by a fall from a horse. The rent in the choroid was seen to occupy a space midway between the disc and the yellow spot, and was crescentic in form, its concavity being directed towards the disc. The rent was marked by a considerable accumulation of pigment. The retinal vessels ran over it without any alteration in their curvature or direction. The pigment occurred six or seven weeks after the accident, and was not the remains of hæmorrhage. Case 2: From a girl, aged nineteen, who had six months before admission received a blow from a portion of an exploding coffee-pot. There were three separate rents in the choroid: one at the yellow spot; the second, a small crescent, above the disc; and the third, a large irregular rent, above the last, and near the periphery.

Mr. T. McArdle exhibited Tumours of the Cerebellum, removed from a child ten years old, who, three days after a fall on his head, was admitted into St. Vincent's Hospital with all the symptoms of cerebro-spinal meningitis. Sections of the tumour showed giant cells, with caseation of the central parts of the tubercular mass.

Mr. McArdle also showed a Toe with Fibroid Tumour attached. The tumour was painless and slow of growth until within a month of its removal. A short time before admission into St. Vincent's Hospital caustics had been applied with the effect of increasing the size and altering the surface of the tumour, as well as deadening the pain.

Mr. Anthony H. Corley exhibited a specimen of Extra-capsular Fracture of the Neck of the Femur. The patient was over eighty years of age. She lived three weeks after the accident, and had more power than usual in turning in bed. There were no signs of severe contusion. She suffered from bronchitis and emphysema, and died rather suddenly. The fracture was comminuted, the great trochanter being split vertically.

Dr. J. Magee Finny showed a specimen of Cirrhosis, or Fibroid Induration, of the Upper Lobe of the Right Lung, in which the disease was strictly limited to that lobe, and had caused it to be converted into a series of cysts, varying in size

from a pea to a small marble. There was a complete absence of the normal alveolar tissue, which was replaced by a dense fibro-cellular tissue of a greyish-red color. The cysts, which as a rule did not communicate with each other, contained a yellow muco-purulent secretion, free from special fetor, and were lined with a mucous membrane, continuous with that of the bronchi. They permeated the entire lobe, giving it a very peculiar honeycombed appearance. The bronchi were slightly dilated in their tertiary division. It seemed as though the alveolar tissue alone, to the almost total exclusion of the pleura, and to a partial exclusion of the bronchi, was the seat of the fibroid change. No other exactly similar case has been observed, and while the lines of demarcation between bronchiectasis and the cirrhosis of Corrigan are by no means so marked as some recent writers (including Juergensen, for instance, in vol. ix. of Ziemssen's *Cyclopædia*) would imply, it was plain that in the specimen the bronchial dilatation had little, if any, connection with the condition of the lobe. The pleura of the right lung was thickened, and adherent to a very slight degree, and sent no fibroid prolongations into the substance of the lung. The patient, a boy aged seventeen, was under observation for about a week, having been admitted to Sir Patrick Dun's Hospital on Dec. 21st, 1882, for a supposed attack of pneumonia of the upper lobe. On Dec. 28th, physical examination showed the presence of what was thought to be a multiple abscess of the lobe, and pleural effusion of a latent type of the left side to the level of the sixth rib. In the course of the case, two days before death, the pleuritic friction was heard as high as the fourth rib. Over a limited extent occupying the third and fourth costo-sternal articulations a double friction sound, synchronous with the impulse of the heart, and increased by pressure, was readily made out, and heard by several observers. It was thought to be of pericardial origin, the inflammation being secondary to extension from the pleura. The post-mortem examination showed that there was no pericarditis, and that its real cause was the impact of the heart against the pleura, which was roughened and granular in its narrow prolongation under the sternum. Dr. Finny noticed the rarity and commented on the clinical significance of this physical sign. The cause of death was syncope, due to the sudden outpouring of fluid into the left pleura and the incautious sitting up of the patient. On the evening before his death the respiration was 28; pulse 120; temperature 102°; and there were no signs of asphyxia. The patient was resting easily on the right side, and expressed himself easier and better than he had been since admission. During the day the fluid had not reached above the fifth rib in the semi-recumbent posture, and there were no symptoms suggesting, not to say demanding, mechanical relief. At 3 a.m. on the 29th, whilst taking nourishment, he was noticed suddenly to become pale and to be bathed in perspiration. He died in an hour. Effusion of a very rapid nature and to a very considerable extent must have occurred during the night, as the pleural cavity was found full of fibrous serum, and the lungs compressed, without enlargement of the side or bulging of the intercostals.

Communications: (1) *Double Gliomæ Retinæ*; (2) *Intraocular Tumour.*

Mr. Swanzy read a paper on *Double Gliomæ Retinæ*, illustrated by a living specimen. The patient was aged two years and a half. His mother first noticed a peculiar appearance in the interior of the right eye twelve months ago, and four months later in the left eye. At the first visit to

the National Eye and Ear Infirmary six weeks ago, a growth was found in each eye of a pale-yellow color. In the right eye it lay deep on the posterior surface of the globe; in the left eye it came most to the front occupying two-thirds of the vitreous humor, and presented a lobulated surface. The vitreous humor in each eye was clear. There had been no iritis, or other inflammatory process, and there was no injection of the anterior parts of the eyeballs. There were not, and had not been, any head symptoms, and in all respects the patient's general health was perfect. He had never had any illness. The only changes since the case had been under observation were a slight increase in the size of the growths and that the right eye had become glaucomatous. However, the child who spoke remarkable well for his age, has lately spoken sometimes very indistinctly and with much rapidity.

Dr. Swanzy also read a paper on a case of *Intra-ocular-Tumour* (illustrated by microscopical sections prepared by Mr. P. S. Abraham). The growth had commenced six years ago, and when removed was, with the eyeball, the size of a hen's egg. It was still covered in front by conjunctiva and atrophied sclerotic, but had grown through the sclerotic above and displaced the eyeball downwards. The greater portion of the tumour was found to consist of a melanotic sarcoma, with round and spindle cells in the usual arrangement. Around the optic nerve, behind the globe, there was a considerable mass of tumour containing less pigment, and in it there was an alveolar arrangement corresponding to Billroth's alveolar sarcoma. At one part of the highly pigmented portion, where it came in proximity to the conjunctiva, there were well-marked alveoli containing epithelial cells, thus, so far, placing the tumour in the category of carcinomatous sarcomata described by Virchow.

SURGICAL SECTION.

A meeting of this Section was held on January 12th, Mr. J. K. Barton, President of the College, in the chair.

Exhibition of Specimens.

Specimens by card were exhibited by Messrs. Wheeler (vice-President), Thomson, and Stokes; and living specimens by Messrs. Benson, Swan, Wheeler, and Croly.

Anæsthetics in certain Surgical Operations.—Trephining in Mastoid and Tympanic Disease.

Dr. Fitzgibbon read a paper advocating the use of anæsthetics in surgical operations upon the mouth, anus, and rectum, and especially in operations for the removal of internal hæmorrhoids. The anæsthetic he recommended was bichloride of methylene, which he had largely used in the foregoing operations, employing Junker's inhaler.—The President corroborated Dr. Fitzgibbon's statement with regard to the facility of exploring the rectum under anæsthetics.—Mr. Hamilton pointed out that rectal surgery had for many years past undergone great modification. He alluded to a paper of his published several years ago, recognizing the advantage of anæsthetics in the treatment of hæmorrhoids. Anæsthetics were, he considered, more adapted to the rational and scientific treatment of rectal diseases than any other department of surgery. Indeed, he did not think that any conscientious surgeon would operate without anæsthetics, which had the advantage in addition of lessening the repugnance that many persons had to such physical examination.—Mr. Thomson observed that from the time he was a

student in the Richmond Hospital almost all rectal operations had been performed under the influence of anæsthetics, except in cases where there was some special contra-indication. His experience of ether as an anæsthetic was so favorable that he did not see any reason to substitute bichloride of methylene for it, especially as it was not so safe as ether.—Mr. Ormsby distinctly preferred ether, and pointed out that statistics were against the use of bichloride of methylene and chloroform. He doubted the propriety of advocating the use of anæsthetics in all cases requiring rectal operations.—Mr. Pratt stated that his experience of bichloride of methylene was very favorable. Its action was much more rapid than that of ether, and the required quantity used much less, especially in protracted operations.—Mr. Wheeler endorsed all that Dr. Fitzgibbon had said in reference to the advantages derived from the use of bichloride of methylene. He thought that the length of time patients remained intoxicated after the use of ether was a disadvantage which was got rid of by the use of bichloride of methylene, and that there was less liability to sickness after the latter. In cleftpalate operations, especially in very young children, its use was indicated.—Dr. MacSwiney alluded to the late Professor Morgan's researches on anæsthetics, and asked Mr. Stokes what anæsthetic he had used in the case of excision of the superior maxilla exhibited previous to the meeting.—Mr. W. Stokes observed that in the case Dr. MacSwiney alluded to ether was used, and he preferred it to any known anæsthetic.—Dr. Kilgariff also gave preference to ether, and enumerated various important operations about the mouth in which he had employed it with success. Dr. Fitzgibbon replied, emphasizing the alleged advantages of bichloride of methylene over ether and chloroform, particularly in operations about the rectum and the mouth.

The Vice-President (Mr. Wheeler) read a paper on Trephining in Mastoid and Tympanic Disease. He related the causes of purulent discharges from the ear, and the necessity for early trephining in diseases of the osseous structures, if not yielding to other treatment within a reasonable time. He recorded the last two cases he operated on; the first that of an old man, seventy years of age (who was present); and second that of a patient, aged forty-one, who suffered from acute inflammation of the mastoid process. Both made good recoveries. Statistics which he quoted showed that nearly all the cases left to nature or expectant treatment died. Having enumerated the various channels through which purulent discharge found its way to the cranium, he advocated trephining in that situation where the mastoid cells and tympanum would be opened and the dura mater exposed—namely, anterior to a line which divides the mastoid process vertically, which would avoid the lateral sinus and the lower border of the temporo-sphenoidal lobe on a level with the external auditory meatus.—Mr. Benson inquired what treatment previous to operation had been adopted by Mr. Wheeler, mentioning that Mr. Pollock and other authorities did not despair of effecting cures in such cases, even when there was caries of the mastoid cells.—Mr. Doyle mentioned cases of mastoid disease that had been successfully treated by making an incision on the mastoid process.—Dr. Henry Kennedy stated that in his experience such cases as had been detailed were not permanently benefited by incising the mastoid process.—Dr. Thomson asked whether Mr. Wheeler had adopted any other treatment than what he had stated in his paper; and also whether in all cases of otorrhœa with tenderness over the mastoid process he would at once recommend trephining.

ing.—Dr. Bennett pointed out that Mr. Wheeler had described his treatment only in cases in which, while there was otorrhœa, there was manifestly disease in the neighborhood of the mastoid process capable of being detected. There were a number of cases where the bone was diseased, and where the disease was entirely remote from the mastoid process.—Mr. Wheeler, in reply, said that the previous treatment in the case of the younger patient alluded to by Mr. Benson was simply syringing the ear. There was evidently disease of the bone. He had not stated they were to trephine without adopting other means, but he had mentioned that if the disease lasted any length of time he would trephine, even in the absence of osseous disease. He had witnessed one case where excellent results had been obtained by incising the mastoid process, but in these there was no disease of the cells. Dr. Bennett had asked if he would trephine in all cases, and if there was a piece of bone diseased at the apex of the petrous portion of the temporal bone whether there would be any possibility of doing good. He (Mr. Wheeler) doubted if diseased bone could be thus diagnosed; but if the person had cerebral symptoms and running from the ear he would be induced to trephine. The operation was not done often enough.

HARVEIAN SOCIETY OF LONDON.

At the meeting of this Society on Feb. 1st, 1883, E. Symes Thompson, M.D., President, in the chair, Mr. W. H. Lamb read notes of a case of Pleuropneumonia, which presented several interesting features. The President, Dr. Ewart, Dr. Hayes, and Mr. Cripps Lawrence joined in the discussion which followed.

The paper of the evening was read by Mr. H. C. Stewart, the subject being "The Treatment of Fevers and Exanthemata by Antiseptics." The author said that his attention had been directed to this subject since the year 1837, when, as a student, he saw cases of glanders and farcy treated with creasote by the late Dr. Elliotson with considerable success. Since that date he had treated cases of small-pox, some of them of most virulent type, with sulphite of soda, the result being decidedly favorable. He found that this drug cut short the usual periods of the different stages, that maturation began and ended earlier under its influence, that the scabs were more quickly thrown off, and with less pitting. For scarlet fever he used a linctus composed of one part of sulphurous acid to seven parts of honey, which he found very efficacious for the throat distress in scarlatina anginosa; measles, typhoid fever, diphtheria, and erysipelas treated with the sulphite of soda or sulphurous acid quickly subsided under the use of these drugs. Salicylic acid, combined with potash, soda, or ammonia, was found useful in catarrh, influenza, and the milder cases of scarlet fever, typhoid fever, and measles; but in the severer cases the sulphites were to be preferred. The author then quoted M. Ramonet, of Algeria, and M. Duplatz, of Lille, who had treated successfully many cases of typhoid fever by enemata of solutions of carbolic acid, of a strength varying from one to fifteen grammes of the crystals to 150 grammes of water. He mentioned the discovery by Ehland, of Stockholm, of a vast number of peculiar cellular bodies in the blood and urine of scarlatinal patients. This discovery had recently been confirmed by Dr. Oesterlony in America, and, if the views of these observers be correct, the infective material of scarlet fever had been discovered.—In the discussion which followed, the President and Mr. Eastes took part, and the author briefly replied.

Discussion on the Effects of the Use of Alcohol in Relation to Disease and Death.

The meeting on Feb. 15th (the President, Dr. E. Symes Thompson in the chair) was devoted to a discussion on the report of the committee appointed for the purpose of inquiring into the Mortality referable to Alcohol.

Dr. Morton, in opening the discussion, remarked that the largeness of the number of cases the committee were able to collect was a matter of congratulation in two respects. First, as evidencing the interest of the profession in the inquiry instituted by the Society; and, secondly, in sufficing to eliminate, as nothing but large numbers could have done, some sources of error to which this inquiry, and all inquiries of a statistical kind, are notoriously exposed. He thought the figure eventually arrived at—namely, 4 per cent., was to be thoroughly relied upon as representing, at least for the metropolis, the proportion of deaths in the causation of which alcohol played some part. In Table B, and the sections based upon it, it is to be remarked that the causes of death set down are the certified causes; and it should be borne in mind that certificates which under the present system are open to the inspection of sorrowing relatives, and perhaps critical insurance offices, do not always express the whole mind of the certifier. As to the immense preponderance of deaths from disease of the liver and other allied organs, it is to be remarked how very small the mortality from these causes would be apart from the results of alcohol, and of residence in tropical climates. Explaining the smaller mortality amongst the alcoholic from chronic pulmonary disorders, the speaker pointed out that the heavy demands of these exceedingly common diseases could not be satisfied after alcohol had exacted its tax in the shape of liver, kidney, and brain disease, which engrossed 150, 20, and 85 respectively out of the whole total of 397 in Class C. The later stage of phthisis might be accounted for by that distinct form described by Dr. Richardson as occurring among hard drinkers.—Dr. Cleveland thought the report remarkable by the absence of any deductions, and asked the *cui bono* of it; there was no question as to the harm done by alcohol, but the report told them nothing they did not know before.

Dr. Norman Kerr remarked that the figures of the report, if applied to the United Kingdom, would make up a total not far short of 50,000 deaths due to intemperance, or 5,000 more than the computation he had made some years since, which had met with much adverse criticism. One benefit resulting from this report would be, that the attention of medical men would be more pointedly drawn to the effect of alcoholic excess on the death-rate of their patients in the future than it had been in the past. The committee, he thought, were well advised in not being too positive in their deductions; it was very difficult to arrive at the truth, both from the personal idiosyncrasy of the observers and the inherent difficulty of the subject. Death certificate counterfoils were no very reliable basis; but he suggested that the Collective Investigation Committee of the British Medical Association should ask 500 or 1,000 medical men in different parts of the country to record simultaneously, for a period of twelve months, the causes of all the deaths occurring in their practices, by which means an accurate approximation might be made of the number of deaths annually caused by personal excess in alcohol.

Dr. B. W. Richardson remarked that deaths from alcohol were seldom or never recorded as such in death certificates from feelings of delicacy to the friends. As to the paucity of deaths from phthisis

amongst drunkards, he agreed with Dr. Morton's explanation, and pointed out that phthisis and alcohol asserted their influence at different times, deaths from the former cause taking place earlier in life, and mostly before alcohol could have exerted its baneful influence. Alcohol could not, certainly, exercise any preservative action from phthisis. He could not understand the lessened mortality from heart disease, and thought there was a want of accuracy in the definition. He had found nothing so common amongst the intemperate as cardiac disease, not so much valvular as structural in nature.—Dr. Fitzpatrick believed that the net scientific value of the report was nil. The inquiry was tainted in its origin by its party character, and he looked upon it as a manoeuvre on the part of certain persons to *exploit* the Harveian Society in the interests of the temperance propaganda. Having quoted a passage from Mr. M. Arnold's speech on "lucidity," to the effect that "there is no other country in which so much nonsense is as firmly believed as in England," he urged the Society not to add to this floating capital of nonsense by affirming on scientific authority that the moderate use of wine, beer, and spirits is unwholesome.—Mr. Eastes said that were not deaths from abdominal diseases amongst drunkards much increased, an advocate of the liquor traffic might have suggested that deaths, and particularly those who would avoid death from thoracic diseases, should take alcohol without stint. In Table 3 of the report the percentage of mortality amongst drunkards from various diseases was compared with that of the entire population of London from the same diseases. As the entire population comprised abstainers, temperate persons, and drunkards, the difference for and against drunkards would be accentuated if their deaths were contrasted with those of the temperate and abstainers only. This would give the former a still lessened percentage from thoracic diseases, and still more striking increase of deaths from abdominal diseases. Further, all persons of Class C in Table 3 were not necessarily greater drunkards than those of class B, nor possibly were all of Class C habitual drunkards. A first debauch might, as in accidents, cause death, and be classed as entirely due to alcohol. These tables told only part of the tale of the effects of alcohol; in order to cover the whole inquiry one must consult the general practitioner, the surgeon, the physician, the physiologist, and last, though not least, the relieving officer of the poor, since alcohol costs money, incapacitates breadwinners, and in other ways brings poverty in its train.—Mr. Burridge said the report would be considered of great value by the actuarial profession, which, for the moment, he had the honor to represent. The report threw additional light on the mortality arising from irregular habits. This was a source of much trouble to insurance offices, and it was necessary to impose a very heavy extra premium, or to decline altogether cases where a suspicion as to habits existed. He pointed out that the mortality amongst publicans was far higher than amongst members of any other trade, the percentage of deaths amongst them being very similar to those of Classes B and C in this report combined. Experience of those offices which had ensured large numbers of abstainers showed that amongst them the actual claims were only 70 per cent. of the expected claims; among the non-abstainers 99 per cent. of expected claims. He concluded by hoping that the Harveian Society would extend their useful labors.—Mr. Stewart, who acted as chairman of the committee, said that one good, he hoped, would result from the report was a more accurate use of terms in filling up death certificates;

he had been much struck with the looseness of phraseology adopted by medical men. Another good was that the profession would watch more closely the effects of alcohol on their patients, and treat them accordingly.—Dr. Francis considered that a similar investigation in India would produce valuable results. Persons come home from that country attributing their ill-health to its climate, but the real cause was that they did not adapt themselves to the climate, but by the use of stimulants taxed their livers to an extent which would be injurious at home, but was disastrous in the tropics; for, owing to the diminished capacity of the lungs for eliminating carbon, that duty fell upon the liver, which under ordinary circumstances, was hardly equal to the strain.—The President explained the reduced number of deaths due to diseases of the heart, kidneys, and lungs, by the fact that the disease of the liver was the most prominent symptom at the time of death, and in the tables of the report only the principal cause of death could be recorded. As to the smaller proportion of deaths from alcohol among women, he suggested that a large number of women were secret drinkers, and managed to keep their secret so well that even the medical man failed to find it out.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

Colloid Cancer of the Peritoneum.—Post-hemiplegic Hemichorea.—Recurrent Fibroid.—Calculus in the Ureter.

THE usual monthly meeting of the above Society was held on January 5th, Mr. Frederick Lawrence in the chair.

Dr. Thorowgood exhibited a patient believed to be suffering from Malignant Disease of the Abdomen. On examination the abdomen was much distended. Slight evidence of localized fluctuation could be detected in the flanks, and he said that when in St. Mary's Hospital last August (the patient was admitted to the West London Hospital on December 13th, 1882), he was tapped by order of Dr. Handfield Jones in the left flank, from which serous fluid was drawn. He is now losing flesh, has a quiet pulse, clean tongue, does not vomit, heart and lungs act normally, and he appears healthy. On feeling the abdomen a hard mass is found below the ensiform cartilage, about two inches by two inches in size; doubtful if this mass moves much in respiration; below this comes a zone of resonance, then across abdomen can be traced at level of umbilicus a chain of hard, tender, irregular masses. Liver dulness somewhat increases upwards. Twenty years ago he came home from India invalided for dysentery, and ten years ago he had slight coughing up of blood. With these exceptions his health has been good. Present illness commenced with enlargement of abdomen five weeks before the admission into St. Mary's Hospital on August 21st, 1882. Paracentesis abdominis was performed, and after that liver dulness extended eight fingers' breadth upwards in right chest. No lumps were felt in the abdomen at this time, but a hard mass below the xiphoid cartilage was believed to be the left lobe of the liver. The urine contained lithates, but no albumen. The case was set down as cirrhosis with ascites, and on Nov. 2nd the patient left St. Mary's Hospital. He says that while in that hospital he had a dose given him which brought away three yards of tapeworm, but not the head of the parasite. Before tapping his abdomen measured 38½ in. at level of umbilicus. Present measurement 34

in. Dr. Thorowgood believed the disease from the first was colloid cancer. At present the functions of the stomach and intestines are not much affected, but the patient loses flesh rapidly, and the prognosis was, in his opinion, anything but favorable. Saline purgatives were given him to relieve congestion and oppression, and at night extract of conium to relieve pain.—Dr. Schacht referred to a case in which a mass could be felt on deep palpation in the hypogastric region which was diagnosed as malignant, and proved at post mortem to be a mass of encephaloid cancer.—Dr. Thudichum asked for a definition of "colloid cancer;" he knew what "colloid" meant, and he knew what "cancer" meant, but he did not understand the combination of terms. As the case under notice was of long standing it was very interesting and important, but he was not clear as to the possibility of diagnosing abdominal cancer in the living human being. Then as to treatment: he could not understand why extract of conium was administered as so little was known of its influence. He questioned whether it contained any alkaloid, and, indeed, whether it had any medical effect whatever. It was not chemically definable.

Dr. Pope said that he knew a case of an old man who had large masses in the abdomen, swelling in both sides, and much obstruction in breathing. There was also localized fluid easily felt in the flank. It turned out to be sarcoma originating in stone and chronic kidney disorder.—Dr. Daniel, referring to the disputed use of extract of conium, said that he preferred morphia as a sedative, because it was more certain in its operation.—Dr. Alden Owles did not regard the comparative absence of pain as weighing much against the symptoms of cancer in the case, as in his experience severe pain was far from being an invariable concomitant of abdominal cancer.—Dr. Thorowgood, in reply, said that it was, of course, possible to have abdominal cancer without pain. This might be a case of sarcoma, but the locality indicated that it was a colloidal form of cancer. He regarded extract of conium as a useful sedative, although it was not clear what was its effective principle, and although its mode of action was obscure.

Mr. Percy Potter showed a case of Post-hemiplegic Hemichorea with Hemianæsthesia, in which there were some peculiar clinical features. The patient, aged thirty-two, had been a soldier, and had always enjoyed good health previously to the present affection. He never had rheumatic fever nor syphilis, nor was there any history of injury to the head. The family history was good, except that his mother had temporary chorea. Eighteen months ago, whilst playing a wind instrument under the tropical sun of India, he became suddenly unconscious, and when he recovered consciousness there was right hemiplegia, without aphasia. This improved to some extent, but the muscles of the legs became atrophied, and the flexors of the foot tonically contracted, assuming, as in paralytic club-foot, the form of talipes equinus. Having returned to England, he was operated upon for this contracture, tenotomy of the tendo Achillis being performed at Netley Hospital three months after the outset of hemiplegia. This did not influence the deformity. Three weeks ago the patient was frightened by a mastiff dog, which knocked him down. Five days after there appeared chorea of the affected side. There was now well-marked right hemiplegia, including the face, without aphasia. The vision of the right eye was defective; the senses of smell, hearing, taste (as tested by aloes and colocynth) were blunted. There was complete anæsthesia of the right side of the face and leg; less complete of arm, trunk, and thigh. The symptoms of chorea

consisted of sudden and unexpected jerks of the right arm and thigh, and right side of face. The muscular movements were quite uncontrollable. Tendon reflex and ankle clonus increased; no cardiac bruit; urine normal.

Dr. James Thompson showed a Tumour removed from a woman, aged thirty-six, after its fifth recurrence. Its situation was in the median line at the border of the hair in the forehead. The size was that of a goose's egg, springing from a base only three-quarters of an inch in diameter. The original tumour was removed in 1869. At least four surgeons had operated. Both caustics and the knife had been used. Dr. Thompson operated with Richardson's scissors, and applied the actual cautery to the foot. A committee was appointed to report upon the character of the tumour. Dr. Thompson also exhibited a Calculus, believed to have been formed in the ureter.

MIDLAND MEDICAL SOCIETY.

At the meeting of this Society, held on Jan. 24th, Dr. E. Malins, President, in the chair, Dr. Suckling exhibited a man suffering from Primary Lateral Sclerosis of the Spinal Cord. Thirteen years previously he had had an attack of paraplegia, from which he completely and readily recovered, and subsequently remained perfectly free from any symptoms of spinal affection for ten years. Two years ago he first noticed a weakness and trembling in his limbs, which had constantly increased ever since. At the present time sensation was intact. There was great exaggeration of knee tendon-reflex and marked ankle clonus. The optic discs were normal. There was a history of previous syphilis.

Mr. Eales showed three cases in which the Lens had been dislocated, in each case inwards and somewhat upwards, as the result of blows on the eye. In the first (a little boy aged four years), the lens still retained its transparency intact, though nearly five months had elapsed since the injury. The pupil, moreover, remained completely dilated, and would not contract even under the application of eserine drops (four grains to the ounce); myopia and astigmatism—due, apparently, to the shifting of the lens—were present. In the second case, a man, aged thirty, the lens was quite opaque, in addition to being dislocated. There was also a rupture of the sclerotic coat just behind and parallel to the corneo-sclerotic junction, the iris being incarcerated in the wound. The eye was blind, and T-2. In the third case, a man, aged eighty-three years, the lens had been opaque and dislocated for thirty years. In spite of the age of the patient, and the long time since the injury, the lens and also its capsule had been removed successfully.

Dr. Malins showed two Ovarian Cysts which he had removed a few days previously. One, a simple one, from a girl, aged sixteen years, weighing, with its contained fluid, eight pounds, was remarkable for the rapidity of its growth, which extended over only three months. The other was of a dark color, and its walls were considerably thickened, and showed signs of much inflammatory action, while the pedicle had become completely severed in consequence of rotation of the tumour causing strangulation of the pedicle.

Mr. Bennett May read a paper on Operative Treatment in cases of Intestinal Obstruction, in which he laid stress upon the difficulty and importance of making an accurate diagnosis in this condition, and alluded to the various operations that a surgeon may be called upon to choose between in his attempts to relieve this condition,

which he arranged in the following order as regards subsequent mortality in an increasing ratio:—(1) Colotomy in the loin; (2) enterotomy, by a small incision in the right groin, through which the first distended and presenting coil of intestine is secured and made the site of an artificial anus, without exploration; (3) inguinal colotomy, by opening the sigmoid flexure in the left groin; (4) laparotomy, by median section, the cavity being explored, the cause of the obstruction removed, and the wound closed again; or laparo-enterotomy, if completed by opening the small intestine. He thought the reasons why enterotomy gave a so much lower death-rate than laparotomy, or laparo-enterotomy, were, first, because the conditions for which it is typically applicable are themselves less acute and lethal; secondly, the injury inflicted by the operation is far less; while, thirdly, it is undertaken earlier, and he regarded it as a compromise between colotomy (which in some cases was the better operation) and laparotomy; and one which many surgeons invariably adopted in all cases where the indications to open the colon were not clear and distinct. There were, however, cases in which laparotomy was the only suitable operation; and in many of these it was wise to open the small intestine as near the lower end of the ileum as possible, and stitch it to the median wound, thus performing laparo-enterotomy, and not to trust entirely to the removal of the apparent cause of obstruction. In many such cases the artificial anus after a while closed, the faeces passing by the natural passage. In impacted gall-stones the results had been uniformly bad, and in this condition, if slight force failed to dislodge the calculus, he would perform laparo-enterotomy. If there was great local pain or tumour, he would not confine himself to the median section, but would open the abdomen near the apparent seat of trouble. In chronic obstruction, if due to obstruction in the small intestine from various causes, such as tumour, etc., and in many cases of obstruction in the large intestine where the cause could not be localized, he regarded enterotomy as the best operation.

YORK MEDICAL SOCIETY.

A MEETING of this Society was held on January 13th, Mr. W. H. Jalland, F.R.C.S., president, in the chair.

Mr. Spencer read notes of a case of Croup, in which tracheotomy was performed. The child did well for three days, when broncho-pneumonia commenced, and rapidly proved fatal.

Mr. Jefferson read a paper on some of the Uses of Plaster-of-Paris in Surgery. After drawing attention to a few practical points in the preparation of plaster-splints—such as the warming of the dry plaster, the use of tiffany bandages, and of strips of Bavarian flannel, the latter covered on both sides with moist plaster, for the purpose of giving additional strength—Mr. Jefferson said that the plaster-splint was to be preferred to the glue, starch, and others, in the treatment of fractures, because it dries and sets quickly, thus securing immobility within a few minutes of application. The splint is invaluable in fractures of the lower extremity, and in all compound fractures. Ununited fractures of the humerus are probably best treated by the same splint, carried from the hand to the axilla, the arm being kept extended. In simple fracture of the lower extremity, whether attended with much, little, or no swelling, the plaster-splint could always be applied at once. In fracture of the femur, where the hip must be included, some difficulty would be experienced un-

less something resembling the crane of a hospital bed existed by which the patient could raise himself. When all swelling had subsided, the splint should be lined with a thick layer of cotton-wool, reapplied and fixed by an ordinary bandage. The method of cutting a window in the splint in the case of compound fracture, was described, with the precautions necessary for rendering and keeping the wound aseptic. With this object the use of salicylic wool beneath the splint, instead of the ordinary flannel roller, was recommended.

Mr. Jefferson also read notes of two cases of Compound Fracture of the Upper Extremity, treated in the manner described, at the York County Hospital. He also referred to twenty-four cases in which osteotomy had been performed by Mr. Jalland at the County Hospital. None of these latter cases required a second dressing, and at the end of three or four weeks, when the dressings were removed, the wounds, with one exception, were found to be healed. In disease of joints where a splint-rest is required, whether in the early stages or after operation, plaster-of-Paris affords the necessary support, while it permits the patient to get about with ease. In the early stages of fungous synovitis of the knee it had been found especially valuable after the limb had been straightened under an anæsthetic, the ice-bag-like action during drying preventing fresh inflammatory effusion. Mr. Jefferson quoted cases illustrating its utility in this form of disease. In illustration of the value of Sayre's jackets, Mr. Jefferson mentioned the case of a boy who had just had one of those jackets applied, making the fifth time within eighteen months. Eighteen months ago he had acute pain and tenderness in the lower dorsal region, with slight displacement backwards of two vertebrae. Two large psoas abscesses, one on each side, were opened. These have now quite healed, and there is not the least pain or tenderness in the affected region of the spine. In fact he may be said to be well.

CAMBRIDGE MEDICAL SOCIETY.

At the meeting on Jan. 5th, Professor Humphry, M.D., F.R.S., President, in the chair, the subject of the Communicability of Phthisis was discussed. On the suggestion of the President the following question had been sent by post-card to all the members of the Society, and Mr. Shield read a short analysis of the replies received:—"Have you known any instances of phthisis being communicated from one person to another?" If no such cases had been observed the answer was merely "No." In the event of instances of the kind having come under observation, the names of the persons concerned, and their relationship, the dates of their disease and the result, and the hereditary predisposition, were to be noted by the observer. Out of sixty inquiries but thirty-eight replies were forthcoming, and thirty-four of these were in the negative. On the whole the experience of the medical men in the neighborhood went to prove that cases of communicability were not by any means common, but the question could only be answered satisfactorily by long, patient, laborious, and trustworthy observation.—In the discussion which followed, Dr. Paget remarked that he had no certain experiences to record. He referred to the old view that a general impurity of the air was productive of phthisis, and quoted Dr. Guy's report on the effect of bad air on printers. He also alluded to the diminution of phthisis which had followed the enlargement and improved sanitation of the barracks in England, as shown by the army sanitation report, and inclined to the view that

there was no specific agency in operation, such as the bacillus.—Dr. Armistead observed that there had been a great decrease of phthisis since cottages had been kept in a more healthy condition and sanitary matters attended to in the district under his supervision, embracing unions with a total population of 80,000.

Mr. Laurence Humphry referred to the statistics of the Brompton Hospital for thirty-six years, with regard to the resident officials, compiled by Dr. T. Williams, from which it appeared that of four resident medical officers, one of whom had served twenty-five years, none had any lung disease, of six matrons none were consumptive, of 150 resident clinical assistants eight became consumptive and five died, but in only one was the disease developed during residence. Since 1867, of 101 nurses only one died from phthisis, and that after leaving the hospital. Before 1867 six died, three of these of phthisis, but only one became so whilst resident, and she had a consumptive sister, and married a consumptive patient from the hospital; she died thirteen years after first joining the hospital, but was not there the whole time. Of thirty-two gallery maids since 1867 none developed phthisis whilst at the hospital. Of twenty house porters five died, but none of consumption. Non-resident:—Of nine secretaries three were threatened with lung disease, but recovered. Of twenty-two dispensers seven died, three of phthisis, one while at the hospital. Of four chaplains three died, none of phthisis. Of twenty-nine physicians and assistant physicians eight died, none of phthisis. At the Chest Hospital, Victoria Park, there had been five resident medical officers during about the last fifteen years; all alive and well. Two matrons; neither consumptive. There were two clinical assistants appointed every three months; none known to have developed lung disease at the hospital. One nurse out of fifty or sixty in the last few years became consumptive while at the hospital and died after a year's illness. Mr. Laurence Humphry thought that if there were evidence of phthisis being an infectious disease, it would appear in the greatest degree in consumption hospitals.—Dr. Latham expressed an opinion antagonistic to the theory of infection, and said if the theory were correct there ought to be more cases in support of it.

Mr. Marmaduke Shield showed a specimen of Thrombosis of the Abdominal Aorta and Celiac Axis.

OBSTETRICAL SOCIETY OF LONDON.

THE annual meeting of this Society was held on Wednesday Feb. 7th, 1883, Dr. Mathews Duncan, President, in the chair.

Perimetric Abscess.—Mr. Griffith showed a specimen of Retro-uterine Perimetric Abscess due to the opening into Douglas's pouch of a number of rectal fistulae, a cause of these abscesses, he believed, not previously described.

Epithelioma of Cervix removed during Pregnancy without causing Abortion.—An account of this case was read by Dr. Godson. The patient, aged thirty-five, had suffered for twelve months from yellow or watery fetid discharge, latterly from hæmorrhage and occasional pain. Till then she had been healthy. The cervix was enlarged and ulcerated; the uterus was mobile. The cervix was removed by the écraseur four days after the cessation of hæmorrhage believed by the patient to be menstrual, no bad symptoms followed. Nine days after the operation a sound was passed into the uterus, and four days after this a fetus of about eight weeks' development was expelled. The author remarked

that he believed the abortion was due to the use of the sound, and not to the operation. He advocated the removal of cancerous growths, if possible, at any stage of pregnancy. His case supported the view that cancer favored the occurrence of pregnancy, the patient not having been pregnant for six years previously. He remarked on the patient's previous good health, the late onset of pain, and the importance of not pulling down the cervix when using the *écraseur*.—Dr. Routh remarked on the advantages of early removal of the disease during pregnancy when possible.—Dr. Playfair thought cancer of the cervix more prone to occur in women in whom that part was previously unhealthy. When pregnancy occurred in a cancerous uterus, the cancer often grew with extreme rapidity. He thought the use of the *écraseur* to amputate a cancerous cervix was the worst way of doing it; by this the superficial part only was shaved off and the diseased base left. The best operation was that of Marion Sims, which he (Dr. Playfair) had done repeatedly, with very satisfactory results.—Dr. Herman thought that if cancer of the cervix favored conception, cases of the complication of cancer with pregnancy would be much commoner than they were. The galvanic *écraseur* not only cut through the cervix, but burnt the tissues on each side for some little distance from the line of division. Where the wire tended to slip, it was his practice to cut with scissors a shallow groove for it to lie in.—Dr. Rogers mentioned a case in which removal of a cancerous cervix was followed by abortion. He thought that in this operation Douglas's pouch might be opened notwithstanding every precaution.—Dr. Edis remarked on the practical importance of the early diagnosis of uterine cancer. Where there was doubt, a second opinion ought to be at once procured.

The business of the annual meeting was then proceeded with. The list of officers nominated by the Council was accepted by the Society, and the President delivered an address.

Editorial.

EXCISION OF TUMOURS FROM THE MEDIASTINUM.

At one of the January meetings of the Berlin Medical Society, Dr. E. Küster read a paper on a Case in which he had removed a Tumour from the Sternum and Anterior Mediastinum; and the case is so important that we are anxious to draw attention to the report of it, to be found in the *Berliner Klinischer Wochenschrift*, Feb. 26th. The patient was a healthy-looking, robust man, aged thirty, who on his admission to the Augusta Hospital did not complain of any illness. He denied any syphilitic infection, and there was no evidence of this diathesis. In the winter of 1881-82 he felt for some months dull pains in his chest, and in April, 1882, he observed a tumour on the right side of the sternum which had slowly increased. He had been treated by iodide of potassium for six weeks, and during that time the swelling had increased. Projecting forwards from, and adhering to, the right border of the sternum was a tumour the size of a goose's egg, which also involved the third and fourth rib cartilages, and dipped deeply

into the chest between them. The surface of the tumour was smooth, and the skin over it slightly reddened. The tumour was elastic and gave a sensation of deep fluctuation; no pulsation was detected in it. Heart and lungs were found to be normal. The tumour was punctured with a fine syringe and a few drops of blood escaped, and the end of the needle appeared to be freely movable in a cavity. The result of this puncture was held to exclude anæurism, the absence of all history or other evidence of syphilis led to the exclusion of gumma, and the tumour was diagnosed to be a sarcoma. On October 27th Dr. Küster proceeded to remove this growth, adopting full antiseptic precautions. The first step of the operation was the raising of a large flap of skin from below, off from the tumour. The third and fourth rib cartilages were cut through, and half the breadth of the sternum was detached with a chisel. A narrow kind of stalk of the tumour dipped down into the anterior mediastinum, and there was continuous with a broad mass. In detaching this deeper part the internal mammary artery was cut, and as it could not be secured by a ligature the bleeding was stopped by acupressure; on peeling the tumour from the right pleura a small aperture was made into that sac, and the lung was seen to collapse immediately; a piece of folded gauze was pressed over this wound, and the tumour finally separated by detaching it from the pericardium, which was not injured. The wound was then closed one end of the piece of gauze over the pleural wound being made to project from under the flap of skin which was pressed down by pads into the gap made by the removal of the tumour. The patient made a good recovery, and was shown to the Berlin Medical Society in December last. No lung complication came on. At first the pulsations of the heart were perceptible, but as cicatrization advanced the hollow became more and more filled up, and pulsation was abolished. The tumour was found to be a gumma; the central part consisted of detritus, and surrounding that was a zone of granulation-tissue composed of round and short spindle-cells, and the outer layers of the tumour were composed of firm cicatricial tissue. Are we to admire or to condemn this operation? Küster admits that his diagnosis was erroneous, but contends that the sequel justified his treatment; and that had he known the tumour was a gumma softening, and degenerated in its centre, it would have been the right course to excise it. For he states that gummatous tumours, encapsuled in cicatricial tissue, and undergoing regressive metamorphosis in the centre, are not curable by iodide of potassium, but only by elimination; while in this position a softened gumma is a source of great danger from its liability to burst into the pleura, pericardium, or one of the great vessels, and cause instant death. He refers to König's case of excision of an osteo-chondromatous tumour of the sternum, in which both pleural sacs and the peri-

cardium were opened, and the two internal mammary vessels were divided. The patient, a woman, aged thirty-six years, recovered. After a short review of the varieties of tumours met with in this region, Küster recommends an operation for cases of dermoid cyst and lipoma of the anterior mediastinum, and excludes the rapidly growing and very malignant lympho-sarcomata of that region. He asserts that with our existing means of treating wounds with the certainty of avoiding sepsis, the only great danger of these operations is the occurrence of double pneumothorax. In some very favorable cases the pleura—one or other—escapes uninjured, but care should be taken to have a compress of carbolic gauze ready to be placed over any wound made into the serous sac. This compress can be withdrawn from the wound as the healing progresses. It is impossible to deny that these cases of Küster's and König's are triumphs of operative skill and surgical treatment, and they demonstrate the possibility of so bold a measure being carried out with success. But should these cases remain as surgical curiosities or as models for future imitation? Opinions will differ. We believe that many will affirm that the operation was quite unjustifiable in Küster's case of a gumma. The history of the case does not afford any evidence that the tumour had proved quite unaffected by a prolonged course of anti-syphilitic remedies, and it is impossible to accept Küster's limitations of the power of iodide of potassium to induce absorption of gummata when either degenerated or encapsuled. And as to his argument of the danger attending gummatous growths in this region, even admitting its truth and force, it is impossible not to feel that the perils of the operation of excision are vastly greater. The operation must always be a desperate one, demanding great operative skill and experience and a complete mastery of the aseptic treatment of wounds, and even then it will be justified only in cases where it is the sole means of obtaining relief from serious disease, and there is a fair prospect that the relief obtained will be permanent.

URINE TESTING.

At two of the London Medical Societies recently demonstrations of methods of urine testing were given, and our columns recently contained an account of two other demonstrations on the same subject by Dr. Pavy and Dr. Oliver. It is a platitude to insist on the importance of this branch of clinical investigation, and yet we do not exaggerate when we say that no part is more generally neglected or perfunctorily made. Sometimes inquiry is limited to a question as to whether the urine is clear or turbid, or it may be enlarged by an inspection of the excretion and the dropping into it of a piece of litmus paper, while if the specific gravity of a specimen be taken and it be boiled to test for albumen, and Fehling's test for sugar be

also applied, most physicians regard the examination as complete. It cannot be too well known that although such an examination gives useful information, it is far from being complete or satisfactory, and its results may be most misleading. The specific gravity of a single specimen of urine is of hardly any value; the total daily quantity should be always examined as well. And, in like manner, to test the acidity or alkalinity of one specimen only of urine without regard to the food taken and the time of the last meal, and to the total daily quantity, is as inadequate as it would be to make a fever chart of a case of ague from a single daily observation of the temperature.

All this is perfectly well known, and yet it is daily ignored in practice, and we hardly hope to produce much effect by again drawing attention to it. At the Pathological Society, recently, Dr. Ralfe, who has already done very valuable work in pathological chemistry, pointed out that it is necessary to go further than determine merely the presence of albumen in urine. The new tests introduced by Roberts, Johnson, Pavy, and Oliver, are all of them valuable, as they enable us to detect very minute quantities of albumen, but unfortunately they do not distinguish between the various forms of albumen. Dr. Ralfe showed that for this it was necessary to supplement them by boiling the sufficiently acidulated urine; this precipitates serum albumen, and at once distinguishes between it and the other varieties. Dr. Ralfe proved the following points:—1. Urine precipitated with Dr. Oliver's ferrocyanide test-paper, and coagulated by heat, contained serum albumen. 2. Urine precipitated by ferrocyanide of potassium, and not coagulated by heat unless a citric acid paper was added, contained alkali albumen or casein. 3. Urine precipitated by ferrocyanide of potassium, but not coagulated by heat till a sodic carbonate paper was added, contained acid albumen or syntonin. 4. Urine precipitated by ferrocyanide of potassium, and not coagulated by heat, and which gave a red coloration on the addition of an alkaline solution of cupric sulphate contained para-peptone. The importance of the heat test is undoubted, and Dr. Ralfe showed how readily and simply this could be employed. For carrying reagents Dr. Oliver's test-papers appear to be the most convenient form yet introduced, and if he would add to those he already makes a sodic carbonate, a cupric sulphate, a sodio-potassio tartrate paper, and litmus paper, his book of papers would be complete. With these can be carried very handily a little square of wire-gauze.

Dr. Southey testified to the value of Dr. Johnson's picric acid reaction for albumen, and stated that its delicacy had been of value in demonstrating the presence of minute traces of albumen as a normal physiological constituent of the urine. We believe that there are no facts to support Dr. Southey's assertion, although we now know that under comparatively slight physiological distur-

bances, and apart altogether from organic change in the kidney, albuminuria may be temporarily produced. Had he limited himself to the statement that albuminuria is not in itself a proof of organic disease of the kidney, he would have been perfectly correct. A long run, a cold bath, or a heavy meal, are among the physiological disturbances that in some will lead to this temporary albuminuria. By this statement he laid himself open to Dr. Mahomed's obvious retort that, if minute traces of albumen are normally present in the urine, delicate tests which prove their presence are misleading to the clinical observer, and should be abandoned in favor of some simple coarser reaction which shows the presence of albumen in morbid quantities only.

Dr. G. Johnson demonstrated at the Clinical Society that his picric acid test may be used not only to detect the presence of minute quantities of sugar with great ease, but also for a quantitative analysis; and his saccharimeter is a convenient apparatus. The test is so delicate that it may be readily used to estimate the saccharoid matter normally present in urine.

We can only hope that the pointed attention called to this matter at our two most practical Societies will have some good effect in assisting practitioners in general to understand better both the exact methods and the great importance of urine testing.

A "BILL OF MORTALITY."

PERSONAL health is as important to the community as to the individual. A nation of sick persons or of infirm invalids would quickly cease to be a nation at all. It may seem superfluous even to assert so obvious and trite a fact, but it has a corollary not less true and not less obvious, the importance of which is far from being practically realized. All sickness and all infirmity entail a national loss, actual and definite, in consequence of which the nation is not only weaker, but is also poorer. We are so accustomed to the presence of disease that we imperfectly appreciate its influence on national prosperity, although we realize to the full its blight on the individual life. Pity stirs benevolence to acts of charity for the relief of suffering, and alarm dispels for a moment the apathy which hinders sanitary progress; but compassion is a limited, and fear an evanescent, motive, compared with the self-interest which, whatever ought to be, unquestionably is the ruling force of public action. The national purse is the only weight which surely excites and persistently maintains the national energy. If the nation realized the extent to which it is impoverished by preventable disease, rendered poorer by definite loss of that wealth of which money is the token, it would bestir itself in the cause of sanitary science in a manner that would quickly yield results, of which at present an approximate conception can scarcely be formed. The loss is not realized be-

cause, like indirect taxation, it does not obtrude itself in its naked simplicity. It is one of the drawbacks to charitable institutions for the treatment of disease that one part of the cost of preventable disease is unperceived. If the whole expense of the treatment of such disease were defrayed by separate taxation, its purpose distinctly specified, the eyes of the public would be opened in an effectual manner to one of the elements, and that the smallest, of the loss which they sustain from this cause. The cost to the community of the treatment of those suffering from preventable disease is not inconsiderable, but it bears a small proportion to the loss entailed by the temporary withdrawal of adult sufferers from the production of national wealth, and by the absolute loss of present and future workers in consequence of the fatality of those diseases. Of the sum to which that total loss amounts, no accurate conception can be formed, but an approximate estimate will certainly startle unreflecting persons. A curious attempt has recently been made in France to assess the loss from one disease. In the course of the discussion on typhoid fever, which still drags its slow length along at the Paris Académie de Médecine, M. Rochard presented an estimate which he had made of the loss entailed by typhoid fever in Paris. Although some of the bases of his calculation are hypothetical, the estimate is of much interest as one of the most careful attempts yet made to ascertain and state the money loss to the nation involved by one of the most common, most formidable, and most certainly preventable diseases.

During the year 1882 typhoid fever caused in Paris 3,276 deaths, out of a total number of 58,674. In 1881 the deaths were 2,120, out of a total of 56,820. Thus, the mortality from typhoid fever was greater by 1 per 1,000 in 1882 than in the preceding year. Moreover, during the past ten years, the total number of deaths has presented a progressive increase. Ten years ago the mortality oscillated between 21 and 23 per 1,000, in 1881 it was 25·37 per 1,000, and in 1882 it was 26·55 per 1,000. Of the 3,276 deaths due to typhoid fever last year, 1,449 occurred in the hospitals and 1,827 at home. The number of cases in the hospitals was 9,361, equal to a mortality of 15·47 per cent. The total cases treated were in hospital for an aggregate period of 240,083 days, giving an average to each of 25 days. Each day's treatment costs the authorities 3 francs 10 centimes, making a total cost of 744,257 francs for the whole number. But it is manifest that the three weeks' treatment in the hospital does not represent more than a part of the time during which the patients would be withdrawn from their occupations. It is not too much to estimate the total incapacity resulting from an attack of typhoid fever at two months—one month of illness, and one of convalescence. Now the municipal statistics of Paris show that more than a third of the victims were men between

fifteen and thirty-five years of age, the exact proportion between these ages being 39.43 per cent. It cannot be an excessive estimate to value the labor of these men at 2 francs a day, taking one with another. The two months each would give a total of 563,660 working days lost by the 9,361 patients; and correspond to a sum of 1,127,320 francs to add to the 744,257 francs expended by the authorities in their treatment, making a total for the hospital cases of 1,871,570 francs.

There are, further, the cases which died at their own homes. If the mortality was the same as in the hospitals, an assumption the least favorable for the calculation, this number of deaths would correspond to 11,830 cases. It cannot be supposed that the cost of the treatment of these patients was less than that of the cost to the authorities of the hospital cases, nor that the total period of incapacity would be less. On the same basis of calculation, we have, for these patients, a loss of 2,360,157 francs, which, added to that for the hospital cases, gives a total loss of 4,231,727 francs.

So much for the bill of the disease. But what of its mortality? Fifteen per cent. of the cases were fatal. That is to say the individuals were lost to the nation, not for two months, but for whatever may have been the probable duration of their lives. It is obvious that such a loss must be incomparably greater than that occasioned by the mere illness. But how can it be assessed? That some estimate is possible cannot be denied. It is true the life of a man, morally regarded, is of incalculable value; but the loss to the community of his productive energy is calculable, had we only the adequate data for the estimate. The value must vary in every country and in every race. By a method which he does not specify, and for another purpose, M. Rochard had arrived at the conclusion that it is not too much to estimate the money value to France of the life of every man of the age of twenty years at 12,000 francs (£480); but as all the victims of typhoid fever do not present these conditions, and as it is necessary to include the lives of little or no money value to the community, he takes 6,000 francs (£240) as the average value of each of the 3,273 lives. These represent, therefore, the enormous sum of 19,656,000 francs, which, added to the cost of the disease, gives a definite total of 23,887,727 francs, or very nearly £1,000,000.

It is evident that the bases of this calculation are to a considerable extent uncertain. Moreover, there are some distinct errors which may reduce in a slight degree the total sum. From the estimate for the month of convalescence, for instance, M. Rochard has omitted to deduct the proportion of fatal cases, to which convalescence never came. But the reduction from these corrections would be comparatively small, and the element of uncertainty does not prove that the figures are too high; they may be below instead of above the true sum. Moreover, it does not follow that by any practi-

able means the whole of these deaths could have been prevented; but that many of them might be certain; and if we consider how large is the mortality from other diseases as preventable as typhoid fever, it is evident that the pecuniary saving which sanitation has the power to effect is enormous. M. Rochard makes, for instance, an assumption which is certainly a modest one. He supposes that, by a combined effort of endeavor and capital, it may be possible to reduce the mortality in Paris from its present figure to that at which it stood ten years ago—21.58 per 1,000, the average of the three years 1872, 1873, and 1874—instead of that which was reached last year. This would be the saving of 11,182 lives, equivalent to an annual saving of 67,092,000 francs. Even if he has taken too high a figure, and estimated each life at double its actual value, there would still remain an annual saving of 33,546,000 francs a year, a sum which represents a capital of no less than 670,920,000 franc (£26,836,800); and this estimate is for Paris only!

The practical lesson is that, whatever be the figures taken, an enormous outlay on efficient sanitary measures may prove to be an actual and great economy, and result in a saving not only of life but of wealth. "Nothing is so costly as disease, excepting death; no waste is so extravagant as the waste of human life."

New Inventions

POCKET MEDICAL EMERGENCY CASE.

UNDER the above title, Dr. T. Frederick Pearse has devised a case which strikes us as a very creditable invention. It consists of a cylindrical box, made of ebony or boxwood, which in shape and size resembles a large drawing-pencil. At one end is lodged a specially contrived and neatly packed hypodermic syringe; the other end is made up of a series of compartments, fitted into one another somewhat like the pieces of an object-glass belonging to a microscope. Each of these compartments is intended to contain discs and perles of certain drugs likely to be required on an emergency, the name and dose of each drug being distinctly marked on the outside of each compartment. The substances thus provided for are morphia, apomorphia, nitrite of amyl (in perles), ergotine, ether (in perles), and pilocarpine. Thus the chief materials for hypodermic medication likely to be required on an emergency—whether for the relief of pain, the induction of vomiting, the arrest of hæmorrhage, or the production of sweating, are supplied; and the addition of nitrite of amyl and of ether is also a necessary provision for sudden attacks of angina, asthma, syncope, etc. The whole forms a most compact case, which can be very readily carried in the pocket, and we can heartily commend it to the notice

of the practitioner as being most useful for cases of emergency not requiring surgical treatment. It has been constructed for Dr. Pearse by Messrs. Arnold & Sons, of London.

Reviews and Notices of Books.

L'Étude et le Progrès de l'Hygiène en France de 1878 à 1882. Par MM. H. NAPIES et A. J. MARTIN. 8vo., pp. 546. Paris: Masson. 1882.

THIS volume was prepared at the request of the Council of the Société de Médecine Publique et d'Hygiène professionnelle de Paris, by its two secretaries, with a view to bring under the notice of the International Congress of Hygiene at Geneva in September last, the progress of sanitary science in France during the four years which had elapsed since the Congress met at Paris in 1878. Considering that the time available for its preparation was little over two months and a half, the great number of subjects brought under consideration, the careful manner in which they have been treated, and the extent of knowledge required for the production of such a sketch, the reporters must be deemed entitled to high praise for their labors, and to have added to their already established reputations as scientific hygienists. The first chapter treats of the hygiene of childhood from earliest infancy through the school period, and under this head the arrangement of the class rooms and the principles on which they should be lighted, the best forms of school furniture, and the system of school gymnastics are discussed. Mention is made, as an instance of true progress, of the formation of a swimming bath at the Lyceum of Vanves—a valuable addition certainly to a school, but one which we should imagine, from the notice taken of it, to be a novelty in France. If we may judge by the recommendations made in 1878 by the Society of Public Health on the subject of "measures of an immediate and general application" required for the schools in France, and which do not appear as yet to have been adopted, we are forced to conclude that they are very far behind this country in their arrangements for the health and comfort of the children, many of those now in operation being very objectionable. The second chapter is devoted to the hygiene of food, and gives an account of the establishment, in 1878 and following years, of municipal chemical laboratories for the analysis of articles of food. The necessity for these laboratories is shown by the fact that of 6,258 samples of food and drink analyzed in the laboratory at Paris during the last ten months of 1881, upwards of 50 per cent. were pronounced bad. In subsequent chapters the hygiene of trades and professions, and of the navy and army are discussed, and under the latter head the necessity for improved barrack accommodation is enforced; the conditions necessary to ensure the health of towns, including the important questions of water-supply and sewerage, and the hygiene and sanitary requirements of the country, are also brought under review. The reports of several commissions appointed by the Minister of Agriculture and Commerce, by the Prefect of the Seine and by the Prefect of Police of Paris, to inquire into the sewerage of Paris and into the effect upon public health of several manufactories in the environs, bear evidence to the existence of a most unsatisfactory condition of affairs in that capital, and fully justify the statements recently made on that subject by our Commissioner in his report upon the typhoid epidemic. The measures neces-

sary to remedy these serious evils have been clearly pointed out by the Commissions above referred to, by the engineers of the municipal service of Paris, and by the members of the Society of Public Medicine, but as yet with little effect. There is evidently a great want of a strong administrative body to carry out the necessary measures of improvement and to enforce sanitary regulations.

A long chapter is devoted to hospitals and similar establishments, and in it an account is given of all the new hospitals erected during the four years included in the Report, illustrated by drawings. In connection with the hospitals for children, there is an interesting account given of an experiment made at the Maternité of Paris. Dr. Tarnier, struck with the success which attended the artificial incubation and rearing of chickens at the Garden of Acclimatization in Paris, conceived the idea that the principle might be applied to the preservation of infants prematurely born. He therefore had an apparatus constructed on the same principle as the "couveuse," with certain modifications, and used it in thirty-five cases in 1881-2. The prematurely born infant was placed in this, and retained for periods varying from one to forty days, the mean being five days. Of the thirty-five infants five died, and the condition of the remainder, on being taken out of the "couveuse," is described as very good in five and good in twenty-five cases. During the four years under review, special carriages for the removal of infectious cases were established in Paris, but on a scale totally inadequate to the services required; and schools were organized for the training of male and female hospital nurses.

A chapter is devoted to the subject of the causes and prevention of epidemic and contagious diseases, and includes the regulations for the sanitary police of animals and the measures of disinfection requisite when contagious diseases occur among them. An account is also given of the steps which have been taken to promote and improve the organization of the public health service in Paris and many of the large towns of France, and a notice of the most recent French works on hygiene. We do not think the book would have suffered by the omission of the programmes of lectures on hygiene delivered at various educational establishments.

It would be impossible in the space at our disposal to enter upon the numerous subjects treated in the Report. We must content ourselves with recommending it to the attention of those interested in the various topics. But they must remember that it professes only to be a study of the progress of hygiene during the last four years in France. It does not lay claim to be a complete treatise on the subject, nor does it make reference to the sanitary conditions of any other country. To those who will take the trouble, it affords the means of an interesting comparison between the conditions bearing upon public health in France and England—a comparison which may furnish useful hints both as to what to do and what to avoid. The volume is illustrated by 229 drawings, which serve to elucidate the various subjects to which they refer, but of which we cannot say much from an artistic point of view.

Medical Diagnosis. A Manual of Clinical Methods.

By J. GRAHAM BROWN, M.D. Edinburgh: Bell & Bradfute. London: Simpkin, Marshall & Co. 1882.

THE author of this manual deserves the thanks of all clinical students (and we may add of teachers

also) for the excellent work he has produced. We have been extremely pleased with the accuracy of the statements it contains, no less than with the careful and methodical way in which the whole book is planned; and we may predict for it considerable popularity in a field which has been long occupied by works far inferior to it in thoroughness and exactitude. One deficiency strikes us—viz., the comparative paucity of illustrative diagrams, which are of great assistance in works of this class, and we may call the author's attention to Eichorst's manual as indicative of the extent to which such illustration may be legitimately and usefully carried. Still, it must be admitted that illustrations are not absolutely essential, and it would be a pity if by their introduction such a book as this, on account of its cost, should be placed beyond the reach of students. As a slight indication of the plan of the work, we may add that, commencing with a chapter on the general aspect, condition, and circumstances of a patient, it passes to symptoms concerning the alimentary system, and then successively deals with the examination of the abdomen, the hæmopoietic system, and the circulatory, respiratory, integumentary, urinary, reproductive, nervous, and locomotory systems; and the author has fully availed himself of what are known as "modern methods" in the description and use of instrumental aids to diagnosis.

▲ *Study of the Tumours of the Bladder.* With Original Contributions and Drawings. By ALEX. W. STEIN, M.D., Surgeon to the Charity Hospital, New York. New York: William Wood & Co. 1881.

TUMOURS of the bladder are of such infrequent occurrence that it does not fall to the lot of any surgeon to see a large number, and himself to acquire such experience as to form a sufficient guide to his fellows. Dr. Stein has had the good fortune to meet with certainly two, and probably four, cases of vesical tumour within a few years, and this has naturally excited in him a considerable interest in this important subject. He has therefore searched for all the recorded cases of bladder tumour, and not the least valuable part of the work before us is the extensive bibliography with which it commences, in which the references are given in chronological order. The tumours are classified into papillomata, myxomata, fibromata, myomata, carcinomata, and sarcomata, and the anatomical characters of each group, with certain etiological and clinical features, are first discussed. A satisfactory microscopical examination of a number of the recorded specimens is unfortunately wanting. The sections on symptomatology and diagnosis contain a large amount of useful information. In the chapter on Treatment a brief account of every recorded attempt to remove a vesical tumour is given, the cases being arranged in chronological order and grouped into females and males. The fact which Dr. Stein insists upon is that these records show that the operation of removal of a tumour of the bladder is a very successful proceeding in the female, and far more successful than is usually imagined in the male. He has been able to find twenty-three cases of this operation performed upon females, in seventeen of which the growths were removed through the previously dilated urethra, and in six by means of an incision of the urethra or of the vesicovaginal septum; of this total, thirteen recovered, two patients were improved, and eight died. The tumours removed included papillomata, myxomata, myomata, and sarcomata. The male blad-

der has been similarly operated upon eleven times; eight times through the perineum, once above the pubes, and twice by supra-pubic and perineal cystotomy. Six of these operations proved successful and five were fatal. The six successful cases include five in which the perineal operation was performed, and Billroth's well-known case of the double incision. The author thinks the perineal operation the more generally available, but also speaks in warm praise of the supra-pubic operation, chiefly because by it the parts are freely exposed to view, and also because it affords facilities for dealing with very large tumours.

▲ *Treatise on the Theory and Practice of Medicine.* By JOHN SYER BRISTOWE, M.D., F.R.S. Fourth Edition. London: Smith, Elder & Co. 1882.

THE steady demand for new editions of this text-book affords sufficient testimony to its worth, and the author himself has been careful to improve each succeeding edition by the introduction of new matter and careful revision of the old. He has thus endeavored to keep abreast with the growing progress of medicine, and we find incorporated in this edition such subjects as an account of the bacillus of tubercle, the mitigation or attenuation of contagion, as well as a summary of Dr. Sanderson's lectures on the power of inflammation, delivered last year at the College of Physicians. The chapter on Ophthalmoplegia has been revised and expanded, and a new article added upon the interesting disease, acute ascending paralysis. We note, also, a considerable increase in the number of illustrations. There is no need to commend this work to students, for it has obtained a well-deserved success, and now holds a firmly established position amongst our text books.

▲ *The Contagiousness of Pulmonary Consumption, and its Antiseptic Treatment.* By I. BURNES YEO, M.D. London: J. & A. Churchill. 1882.

Dr. Yeo has reprinted with several additions, in the form of appendices and notes, the text of two lectures delivered at King's College Hospital last summer. The lectures are written in a clear and comprehensive style, and they review the arguments in support of the notion that tubercular phthisis is communicable, as derived from experimentation on animals, from a certain amount of clinical experience, and, lastly, from the discovery of Koch, which may make the past year memorable in the history of pathology. We think, however, that until more clinical facts are available of the actual transmission of pulmonary tuberculosis from one individual to another, it is somewhat premature to deal with the subject, except as a matter for speculation, and we do not think Dr. Yeo would go further than that at present. It is encouraging to learn from him of the value of antiseptic inhalations in phthisis, for the mode of administering which he gives ample details.

▲ *Pharmacopœia of Selected Remedies, with Therapeutic Annotations, etc.* Arranged as a Handbook for Prescribers. By EDMUND A. KIRBY, M.D., M.R.C.S. Eng., late Physician to the City Dispensary. Sixth Edition, enlarged and revised. London: H. K. Lewis. 1883.

Dr. Kirby's book has, in this edition, been entirely remodelled, and several changes have been introduced which tend to make it even more useful to practitioners engaged in private practice.

than it was in the older editions. The *ateria medica* has been compiled from the British and American Pharmacopœias, and, in addition, includes many valuable non-official remedies which are largely employed, and have gained considerable reputation, in English and American practice. An Index of Diseases and Remedies is also appended—a plan followed in all the most practical works on therapeutics. The object which the author had in view—viz., to supply the private practitioner with therapeutical data as to some of the more important remedies used in the metropolitan hospitals, and to put into his hand the most efficient formulæ of remedies for the general treatment of disease—has been fully attained. The book is well written, well arranged, well got up, and eminently useful and practical.

Injuries of the Spine and Spinal Cord. By HERBERT W. PAGE, M.A., M.C. London: J. & A. Churchill, 1883.

In all, save 7, of the 234 cases of railway injury tabulated by the author at the end of this interesting volume, there was no evidence of injury to the spinal cord or its membranes, so that it can hardly be expected that the work throws much light on the nature of the obscure troubles which follow "concussion of the spine." The genius of the author is destructive rather than constructive, and although he urges many objections to the views put forward by previous writers, he does not add much to the symptomatology or pathology of his subject. Glancing through the outline of the cases which he has tabulated, one cannot but be struck with the fact that the clinical picture drawn by previous writers, and especially by Mr. Erichsen, is strongly supported by them. We encounter again and again cases in which the sufferer who has been in a collision begins by thinking he is not hurt, and very possibly has assisted relieving others, or has walked some distance. Then perhaps he vomits, and in a day or two finds himself unable to work, and takes to his bed. He complains of pain, stiffness, and hyperæsthesia of the back; cannot bear the light, becomes hysterical, grows thin and haggard, and has perhaps numbness in the legs, difficulties of vision, and aching pains throughout the body. No less than 145 out of the 234 cases complained of their backs or their spines. Mr. Page doubts whether the symptoms referred to the back indicate trouble of the spinal cord. He is inclined to think that this may all be due to sprain of the vertebrae and their ligaments, or the spinal muscles, and he would use the term "traumatic lumbago" in preference to "concussion of the spine." Persistent tenderness of particular vertebrae, pins and needles, numbness and weakness of the legs, stiffness and hyperæsthesia of the back, and even difficulties of micturition and defecation, may all be accounted for by direct injury to bones or muscles, and in Mr. Page's opinion are more often due to this cause than to troubles of the spinal cord or its membranes. Possibly Mr. Page may be right, but it must be confessed that he does not appear to have been at much trouble to prove what he asserts. Recent pathologists and physiologists have taught us that many symptoms—such as vomiting, failure of nutrition, troubles of vision, vasomotor disturbance, joint troubles, and other symptoms not hitherto supposed to be commonly connected with derangement of the central nervous system—are in reality dependent upon definite lesions of definite tracts of the spinal cord, and modern methods of investigation have shown us how we may detect lesions of the cord long before

they become gross and palpable. Mr. Page has but a poor opinion of modern methods of investigation. He does not think that the dynamometer is of any use in detecting the consistence or inconsistency of paralysis true or false; the electric test is so often ignorantly used and requires so much care and knowledge that he scarcely thinks it worth while to ascertain whether adjoining or corresponding muscles vary in irritability; skin reflexes and tendon reflex are barely mentioned by him; the careful examination of derangements of sensibility and their limitation or otherwise to particular nerve areas is a matter hardly worth inquiring into, and we cannot gather that the ophthalmoscope has been methodically and systematically used by him. "Common sense," in Mr. Page's opinion, is the best and surest guide in the examination of railway injuries. "Common sense" has so long been in the habit of displaying its uncommon ignorance in the witness box that we trust it will soon give way to men of the modern school who have tried to make themselves familiar with the symptoms accompanying diseases of the spinal cord and the best means of investigating them. We have long felt that a fruitful field is open in this direction, and Mr. Page has left it open. His speculations may be right, but if so he might have done much more to prove them right.

Notwithstanding our unwillingness to receive without question all that Mr. Page professes to teach, we confess to having been much interested in his book, and we should advise all who are working at the subject of which it treats to read it, for it is well written and is full of literary research. In the second chapter, on Concussion of the Spine, the author runs a tilt at Mr. Erichsen. This chapter is in very doubtful taste, and does much to weaken the book. Polemical writing belongs to the worst traditions of a bygone age, and is wholly out of place in a scientific discussion.

Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris, 1880. Paris: Asselin et Cie. 1881.

THE Paris Society, composed of physicians and surgeons of the various hospitals, publishes its official record in the pages of *l'Union Médicale*, just as the Société Anatomique has its Proceedings recorded in the *Progrès Médical*. When completed, these Proceedings are issued in the form of a volume, and that now before us comprises the session of 1880. One of the chief features of this Society is its quarterly reports on prevalent diseases, which, as regards Paris, are contributed by M. Ernest Besnier, and form a very valuable record. There are also similar reports from some of the principal towns, as Lyons, Bordeaux, Marseilles, Toulouse, Rouen, and Havre. Amongst the most notable papers are those on Strumous Ulceration of the Velum Palati associated with Pulmonary Tuberculosis, by M. Laboulbène; Multiple Sarcomata, by M. Millard; a memoir on Salicylate of Soda in Typhoid Fever, Facial Erysipelas, and the Symptomatic Fevers, by Dr. Hallopeau; Pulmonary Tuberculosis and Scrofula, by Dr. Grancher, a subject further treated of by MM. Féréol, Labbé, Cornil, Damaschino, Thaon, Ferrand, and Rendu, in separate papers during the session. Amongst the memoirs appended to the volume is one on Cerebral Syphilis, by Dr. Fournier; on the Treatment of Typhoid Fever by Calomel, Salicylate of Soda, and Sulphate of Quinine, by Dr. Hallopeau; on Ulcerative Endocarditis, by Dr. Ferrand; and on the Parasite found in the Blood in Malarial Fevers, by M. Damaschino.

The Student's Handbook of Forensic Medicine and Medical Police. By H. AUBREY HUSBAND, M.B. Fourth Edition. Edinburgh: E. & S. Livingstone. 1883.

THE rapidity with which the three previous editions of this little book have been exhausted is a sufficient proof that Mr. Husband by writing it has met a want which is felt by a great number of students. The facts contained in it are as varied as they are numerous, and comprise the whole range of medical jurisprudence, toxicology, hygiene, and sanitary government, if we may be allowed to use such an expression. The book is a most praiseworthy collection of facts extracted from the writings of a great number of authors. It will form a handy book of reference, but we doubt whether it is a good book to place in the hands of a beginner. A man with a good memory might by diligent application master all the facts contained in it, but he would run a risk, we think, of being little more than a parrot at the end of it. Students require not only facts but illustration of facts, and every student's book should be planned so that it will cause him to be interested in the subject in hand and to reason upon it. To those who have already mastered the subjects treated of, Mr. Husband's work will prove a valuable book of reference, and its utility in this respect would be increased, we think, if the matter, instead of being classified according to subject, were arranged alphabetically so as to form a sort of dictionary.

The Germ Theory of Phthisis verified and illustrated by the increase of Phthisis in Victoria. By WILLIAM THOMSON, F.R.C.S. Melbourne: Sands & McDougall. 1882.

THE author of the present brochure has raised many important questions—important not only in relation to medical knowledge, but also to the welfare of a young and thriving colony of the British Empire. The writer appears to us to be altogether too positive in most, if not all, of his assertions. It is also a matter for regret that the paper should have been written with such evident bitterness.

In 1876 Mr. Thomson published a pamphlet, entitled "The Histo-chemistry and Pathogeny of Tubercle," in which he advocated the doctrine that the proximate cause of phthisis was a micro-zyyme. We gather from the present essay the notion that Mr. Thomson claims priority of discovery over Koch. It is true that Mr. Thomson also professes a large amount of modesty; but his modesty is so obtrusive in its reiteration that one may fairly doubt whether an undercurrent of jealousy does not permeate the whole. We shall have occasion to quote a few passages which seem to warrant the conclusions we have above stated. "While never dreaming to undervalue the noble work done by Koch, or hint about priority and originality, the writer merely states what is a plain matter of fact, that in 1876 his pamphlet was sent addressed to very many medical savants and university libraries in Germany." When the pamphlet of 1876 was published, it would appear to have been received with violent animosity by nearly everybody in Victoria; and no doubt the author had been subjected to many remarks likely enough to make him retort in an equally vehement spirit. But we must allow that Mr. Thomson has opened up matters in relation to the communicability of phthisis which are full of pregnant meaning, for the Victorians at least.

We may say at once that the author is a firm believer in the bacterial origin of pulmonary con-

sumption, as well as in its contagiousness; and in the latter part part of the brochure he instances many examples of supposed transference of phthisis. After stating that of all deaths from all causes that occurred in adults in Victoria in 1880, between the ages of fifteen and forty-five, one in three was from common consumption, the author observes, "Surely this high death-rate gives the highest importance to the discovery [of the tubercle bacillus] for the people of Victoria, particularly as the cause can be so readily attacked, and its ravages entirely prevented." This last sentence will probably not quite concur with the ideas of many; and the view of which it is the expression is one of the noteworthy points in the essay.

Mr. Thomson seems to have entertained the idea for some years that phthisis was contagious. In 1870 he wrote an article in which he incorporated nearly all the aspects of the question which he now so strenuously advocates; and which he believes to see so remarkably verified by the latest discoveries of Koch, Baumgarten, and others. If we entirely give ourselves up to the doctrines, which are now considered to be very plausible, we may go with Mr. Thomson so far as to believe that phthisis has been imported from England into the Victorian colony, where it has devastated the ranks of the aborigines, in very much the same manner as measles is allowed to have done under similar circumstances in various places. That accusations of a weighty nature are thus levelled at the heads of the physicians of the mother country, as well as at those of the authorities in Victoria, including among them the Board for the Protection of Aborigines, there can be no doubt. And if we view the statistics, presented by Mr. Thomson, in the light he would have us read them, then the accusations will be seen to be fair and honest. The numbers show that, in the decade immediately above puberty, there is an alarming increase in the death-rate from phthisis not only of the new arrivals, but also of the native-born inhabitants; further, the number of individuals dying of consumption is shown to be absolutely and relatively larger in the years ending with 1881 than in the years beginning with 1871. It was thought by many, and seemed to be the general opinion of the Institute of Actuaries,¹ that Mr. Thomson's statistics, garnered from the hospitals of Melbourne, were not properly representative. It was alleged that Mr. Thomson forgot that almost all the cases occur in Melbourne, probably not only from the reason that they originally lived there, but because sick people naturally go where hospital and medical aid can be most readily gained. To these objections Mr. Thomson replied that he had been careful to sift the cases, and had made the proper deductions and allowances. The latest Victorian year-book, which we presume is an authenticated document, shows conclusively that the number of deaths assigned to phthisis has increased, and that not in one part, but over the whole of Victoria. Mr. Thomson is much struck with the increased rate of mortality from phthisis occurring just after puberty; he advances his explanation of the phenomenon in a positive manner.

This leads us to notice another feature of the contents of this paper. The physiology and pathology therein contained appear to us to be of a crude kind; the author endeavors to be more explicit than we believe physiological doctrine warrants. Of this sort are such opinions as are next indicated. Nicotine, as present in smoke, and in alcohol as taken in ordinary drink, are alleged to be destructive of the bacilli of tubercle; the author states that meat, from animals dead of bovine tuber-

¹ See Insurance Record, April 14th, 1882.

culosis, would cause tubercle in man and does produce it, except where alcohol is likewise taken. Further, *climate* is emphatically denied to have anything to do with the production or prevention of consumption. The author perhaps eclipses himself when he gives the *rationale* of the increased death-rate of phthisis, just after puberty. This explanation is not to be found in a hereditary tendency, but consists in an anatomical alteration, whereby a pus cell (laden with bacilli) which could not get into a pulmonary alveolus in childhood, is able to penetrate to that chamber when the advent of puberty shall have widened up the passage thereto? The most interesting and important food for our mental digestion is unquestionably the subject of the possible importation of phthisis into the Victorian colony.

Medical Annotations.

"Ne quid nimis."

DANGERS OF AERATED WATERS.

It is our duty once more to direct our readers' attention to the danger of common aerated waters. The aeration has of course no effect on the quality of the water, and as the consumer cannot judge for himself in the matter, he is exposed to most serious risk if, as sometimes happens, bad water has been used in the manufacture. There is comparatively little danger with aerated waters made in large towns, because as a rule the town water-supply will be used, and the town water-supply is seldom very bad. But in country places supplied by streams or shallow wells there is constant risk that the maker may have chosen the most convenient source without regard to its quality. If the only available water-supply is doubtful in quality, it should be carefully purified before aeration, either by distillation or at least by prolonged boiling and filtration.

OLFACTORY MEASUREMENTS.

VERY interesting facts have been ascertained regarding the time required for the stimulation of the various organs of special sense, and for the perception of the results of the stimulation. The time is measured from the commencement of the stimulation to the moment at which the individual makes a signal that he has perceived it. The measurement has been made for auditory, tactile, visual, and gustatory sensations; but until recently no observations have been made on the sense of smell. This defect has now been supplied by two independent investigators, Dr. Buccola, of Turin, and Dr. Beaunis, of Nancy, who have arrived at results almost identical. The conclusions of the latter have recently been published in the *Gazette Médicale de Paris*. In these experiments the odorous substance was placed in a closed bottle. If not a liquid, it was dissolved in alcohol or water. Two holes were made in the cork of the bottle, and through these two tubes were passed, one reaching nearly to the level of the liquid, the other ending in the upper part of the flask. The end of the former was connected with an india-rubber injector, and the end of the latter tube was fitted with a suitable extremity for introducing into the nostril, stops being placed so that the odor should not escape until a desired moment. The compression of the injector drove a current of air from the interior of the bottle into the nostril. Another tube of the same length, communicating

with the cavity of a tympanum and writing lever, serve to register the exact moment at which the wave of air reached the nostril, and an electrical signal was registered by pressing down a button at the moment when the sensation was perceived. A considerable time was necessary between different observations with the same substance, because otherwise the moment of sensation could not be accurately determined. The interval which elapsed was as follows with the several substances enumerated:—Ammonia, .37 sec.; acetic acid, .46 sec.; camphor, .50 sec.; assafetida, .52 sec.; sulphide of ammonium, .54 sec.; chloroform, .56 sec.; sulphide of carbon, .59 sec.; valerian, .60 sec.; mint, .63 sec.; carbolic acid, .67 sec. Doubtless the different substances have a different mode of action on the olfactory nerve, and thus the variations are explicable.

WOUNDS OF THE HEART.

THE surgery of the present day is undoubtedly aggressive. The intra-thoracic organs had been long beyond the pale even of minor operations, but excision of the lung has recently been proposed on experimental grounds as an operation practicable, at least in certain cases; and now the principle has been maintained by Block, on the same grounds, that wounds of the heart should receive surgical treatment, similar to that which would be given to a wound of an external part. He recently pointed out, to the German Surgical Society, that death from wounds of the heart is usually due to asphyxia from effusion of blood into the pericardium, or to the loss of blood, or to damage to the motor ganglia of the heart, or to obliteration of the coronary artery. Hesitation in opening the thoracic cavity leads the surgeon at present to allow the patient to die when he might be saved from death by asphyxia by a simple incision into the pericardium, and from death by hæmorrhage by an equally simple suture. He has endeavored to show by experiments on dogs and rabbits, that the suture of wounds of the heart is a relatively inoffensive operation, which can be successfully carried out in the space of three or four minutes. In four animals the two pleural cavities and the pericardium were opened for a short time, and all survived—a proof that such interference can actually be borne by animals. The opening of the right and left ventricles and the compression of the entire heart necessary to close the wounds was also borne for some time. A laceration of the cardiac muscle, the opening of the three thoracic cavities, and a suture of the lung to close the openings into the pleura, were also borne by a dog, which, in a vigorous state of health, was presented to the Society. In order to hinder the escape of blood during the suture the apex of the heart was seized and pulled so strongly that the pulse and respiration ceased, so that it was possible to operate, the heart being completely at rest. Not a single animal died in consequence of this manipulation. A less degree of traction, insufficient to affect the pulse or respiration, suffices to close the wound, so that the hæmorrhage ceases. Three animals were shown which had undergone this treatment.

ALKALOIDS IN HUMAN SALIVA.

DURING recent years the influence of saliva in the domain of experimental pathology has been one of considerable prominence. We need only refer to the researches of Pasteur and other French observers to confirm the truth of this. In 1881 Gautier believed he had discovered some chemical bodies resembling alkaloids in the healthy human

saliva. These bodies, when injected into the tissues of animal organisms, produce effects, best seen in birds, like those caused by the venom of serpents. Odo Buiwid has attempted to verify and extend the observations of Gautier, but without success. He does not directly dispute the presence of the alkaloids, but inoculations performed on pigeons, moles, and frogs have been productive of singularly negative results.

BODY-SNATCHING IN AMERICA.

We regret to learn that the horrible practice of body-snatching is carried on in some American cities. There was quite lately a painful discovery of this kind made in Philadelphia, and a criminal action was brought against the demonstrator of anatomy at one of the leading medical schools in that city. Now we learn that there is great excitement in Baltimore, owing to the discovery that vaults and graveyards all round that city are devastated, and the bodies of the recently buried carried off to the schools for dissection. There is of course only one method of stopping this revolting practice, which can commend itself to thoughtful persons, and that is to grant proper facilities for the supply of subjects for dissection. The experience of all the enlightened communities who have adopted this practice shows that it is quite efficient in abolishing altogether the crime of body-snatching.

NEPHRECTOMY IN ITALY.

DR. SPADARO reports (*Gazzetta degli Ospitali*, Feb. 18th, 1883) that five operations for removal of the kidney have been performed in Italy: the first by Urbinati, of Cesena, the second by Raffa, of Rovigo, the third by Clementi, of Catania, the fourth by Novaro, of Turin, and the fifth by D'Antona, of Naples, the three last being successful. Professor D'Antona's operation was performed Dec. 20th on a married lady aged twenty-six, by a curvilinear incision in the left loin. Pus was found around the kidney, which was changed into a bag containing matter. The artery and vein were secured in one ligature, the ureter in another, while a third ligature on the proximal side of the others included all those structures. Perchloride of iron was applied to the stump, and iodoform sprinkled into the wound, which on the suggestion of Professor Palasciano, was not sutured. According to the last report (twenty-fifth day after operation), the wound was granulating rapidly, and the patient progressing to complete recovery.

CRUELTY IN SPORT.

MR. ANDERSON, Sir Frederick Milbank, Mr. Samuel Morley, Mr. Jacob Bright, Mr. Passmore Edwards, and Mr. Buchanan, have brought in a Bill (which has just been committed *pro forma*) to amend the Cruelty to Animals Acts, 1849 and 1850, so that the provisions of those statutes may be extended to the prohibition of cruelty in sport to "any vertebrate animal, whether of domestic or wild nature, kept in confinement or captivity." The principal aim of the projected measure lies against pigeon shooting from traps or liberated by the hand; but there can be no question that, as the Bill is drawn, it will interdict the hunting of "carted deer" and "bagged foxes." These secondary prohibitions are much deprecated by Lord Walsingham and others, and efforts are being made to influence the "Press" and, through it, public opinion against the measure. With the keenest appreciation of the pleasures of sport in its true sense we most heartily support the Bill as it stands. Trapped pigeon shooting and hunt-

ing carted deer are not sport. We see nothing to qualify in the measure, and we should be glad to see retained the second clause—which defines the word "animal" to include any vertebrate animal kept in confinement or captivity—and which it is proposed to omit. The shooting of scared pigeons let loose from traps has long been a scandal, and by the decision of the Legislature is now doomed. In the interests of true sport—that is, the shooting and hunting of wild animals—it is of the highest importance that false "sport," wrongly so-called, and debasing to the public mind, should be abandoned; and, as it would seem, the only way to bring about its abandonment was to move Parliament to interdict it by law. This has now been attempted, and our best wishes are with the promoters of the measure, albeit we should have been glad to see the names of Members of the House of Commons known in sporting circles at the back of the Bill. Probably Lord Walsingham's alarm lest the Master of the Buckhounds should hereafter be fined five pounds for breaking the law, under the proposed new Act, is shared by gentlemen, who must surely sympathize with the main purposes of the measure, although they may demur to certain of its collateral effects.

VAGRANCY.

THE difficult question as to the treatment of vagrants has again arisen; and though perhaps the revelations disclosed at the Croydon Petty Sessions with regard to the management and conduct of the inmates of the vagrant ward at the Croydon Union may result in the establishment for a time of better discipline and more efficient supervision of the casual wards of our workhouses, still it is to be feared that the improvement will be only temporary and superficial. The law regarding the subject of vagrancy needs thorough amendment, and some better means of distinguishing between the *bonâ-fide* homeless wanderer or traveller and the professional vagrant and mendicant requires to be established. That a large army of able-bodied but idle and dissolute men are housed and fed daily at the expense of the ratepayers is a scandal which ought to be suppressed with a strong hand. The actual number of wanderers on the road that are really deserving of substantial aid is, we believe, inconsiderable; but it is a great misfortune that those whom temporary necessity obliges to travel on foot from one place to another should be compelled to herd at night with debased and profligate companions; and no proceeding is more likely to increase the number of vagrants already in existence than the present arrangement for the reception and treatment of casuals. There ought to be no difficulty for people whom temporary distress or want of employment compels to roam in search of work to obtain from their last employer, or from some respectable and responsible person to whom they are known, a certificate stating the circumstances under which they were driven to seek for shelter during an enforced pilgrimage. Were such a certificate endorsed by the police, and allowed only to remain in force during a period simply sufficient for the accomplishment of the journey, many of the present evils might be removed. The certificate should entitle the bearer during its continuance to a clean and decent night's lodging and a substantial evening and morning meal at any workhouse on the route, and the testimony of the master of each workhouse to the good conduct of the sojourner should be attached to the document before his departure the next day. Such a wanderer might, we think, be excused the usual task-work of stone-breaking. The professional vagrant, on the other hand,

ought in all cases to give an account of his antecedents for at least a fortnight beforehand, and have his conduct at the various unions recorded on a certificate. If after a definite period he were found still wandering about the country, he ought to be handed over to police authority and dealt with as an incorrigible rogue and vagabond. Whether it be practicable or not thus to separate the two classes of vagrants we are not in a position to determine, but are certainly of opinion that the present system of allowing persons to roam without control and without supervision from village to village and from parish to parish is one full of danger to society generally, both from a moral and a sanitary point of view. The latter aspect of the case has not been considered as fully as its importance deserves, but very slight reflection shows how likely infection is to be disseminated by these nomads. In the case of the spread of cattle disease we believe this has been recognized. At the present moment, when restrictions are being placed on the removal of cattle, it seems anomalous that this human agency for spreading disease has not been controlled.

LIME-LIGHT FOR TEACHING PURPOSES.

At the meeting of the University of Durham Medical Society, held on the 7th of February, a demonstration was given on the adaptability of the lime-light for teaching purposes. The objects shown were diversified in order to bring out the capabilities of the instruments, which comprised the asphengoscope, the lime-light microscope, and the lime-light sciopicon. The screens used were one of tracing-paper for transmitted light (for the asphengoscope), one of linen (for the sciopicon), and one of chalked linen (for the higher powers of the microscope). By means of the asphengoscope (for the projection of solid and opaque objects), an image four or five feet in diameter could be thrown upon the screen when the object was placed in the focus of the lens of the instrument. Some of the objects were selected as being too small to be shown to a class under ordinary circumstances; others as indicating how plates from books, drawings on cards, photographs, etc., might be substituted for the large and costly diagrams usually employed in teaching. Coins, the works of a watch, the surfaces of the astragalus, the palate bone, preparations of the internal ear, calculus vesicæ on section, crystals and minerals, moths and beetles, pencil and pen and ink sketches on cards, crayon drawings on slate (appearing as on a black ground), plates in books on chemistry, operative surgery, and ophthalmology, and photographs were exhibited. It was shown how a set of diagrams for a full course of lectures could be carried in a pocket-book. The chief drawbacks to the instrument are its cumbrousness and its inadaptability for objects of more than 3 in. square, or of unequal surface. The lime-light microscope was next shown, the apparatus consisting of an ordinary objective which was supported by an arm on a carrier fitted with diaphragms, etc. (like the stage of a microscope), screwed into the front of the lantern in place of the lantern lens, as nearly as possible in the focus of the condenser. The light took the place of the mirror of the microscope; no tube or eye piece was used. With a No. 4 Hartnack a brilliant disc eight or ten feet across was obtained, and the details of histological and botanical slides were clearly brought out; a $\frac{1}{4}$ in. objective was also used, a smaller disc being obtained. Lastly, the sciopicon was utilized for the demonstration of transparencies, its chief advantages being its compactness, its wonderfully brilliant light, and

more especially its arrangements for the placing of the object and for focusing. The transparencies included pencil, crayon, and pen and ink drawings, and water-color sketches on glass. Fine ground glass was used for drawing on, and was subsequently rendered transparent by coating with Canada balsam. It was shown how by the superposition of several slides of this kind successive layers in an anatomical region could be shown either separately or in combination. As, for example, the relations of the thoracic wall and the heart, lungs, and great vessels. This instrument was shown by Mr. Williamson, F.R.C.S., and the asphengoscope and microscope by Dr. Mears, the apparatus being kindly arranged by Mr. Dunn, M. Sc., of the Durham University College of Physical Science.

ICHTHYOL.

DR. P. G. UNNA, of Hamburg, has lately been experimenting on the dermatotherapeutic uses of a substance called ichthyol, obtained by Herr Rudolph Schröter by the distillation of bituminous substances and treatment with condensed sulphuric acid. This body, though tar-like in appearance, and with a peculiar and disagreeable smell of its own, does not resemble any known wood or coal tar in its chemical and physical properties. It has a consistence like vaseline, and its emulsion with water is easily washed off the skin. It is partly soluble in alcohol, partly in ether with a changing and lessening of the smell, and totally dissolves in a mixture of both. It may be mixed with vaseline, lard, or oil in any proportions. Its chemical constitution is not well established, but it contains sulphur, oxygen, carbon, hydrogen, and also phosphorus in vanishing proportions, and it may be considered comparable with a 10 per cent. sulphur salve. Over ordinary sulphur preparations it has this advantage, that the sulphur is in very intimate and stable union, so that ichthyol can be united with lead and mercury preparations without decomposition. Ichthyol when rubbed undiluted on the normal skin does not set up dermatitis, yet it is a resolvent and in a high degree a soother of pain and itching. In psoriasis it is a fairly good remedy, but inferior to chrysarobin in *P. inveterata*. It is useful also locally in rheumatic affections as a resolvent and anodyne, in acne, and as a parasiticide. The most remarkable effects, however, were met with in eczema, which was cured in a surprisingly short time. From an experience in the treatment of thirty cases of different kinds—viz., obstinate circumscribed moist patches on the hands and arms, intensely itching papular eczema of the flexures, and face, infantile moist eczemas, etc.—he recommends the following procedure. As with sulphur preparations, he begins with a moderately strong preparation, and as he proceeds reduces the strength of the application. For moist eczema weaker preparations (20 to 30 per cent. decreased to 10 per cent.) must be used than for the papular condition (50 per cent. reduced to 20 per cent.), and the hand, for example, will require a stronger application than the face, and children a weaker one than adults; but ichthyol may be used in any strength from a 5 per cent. to a 40 to 50 per cent. application or undiluted. For obstinate eczema of the hands the following formula is given as very efficacious. R Lithargyri 10,0; coq. c. aceti, 30,0; ad reman, 20,0; adde olei olivar., adipis, of each 10,0; ichthyol 10,0. M. ft. ang. Until its internal effects are better known caution is advised as to its very widespread application, although Herr Schröter has taken a gramme with only some apparent increase of peristalsis and appetite.

"CRAMMING" AT SCHOOL.

THE subject of "cramming" at school has occupied a large share of public attention lately. The setting of home lessons, which, besides over-tasking the pupil, have usually to be prepared under the direction of the parent and not by the teacher, is the feature which causes most dissatisfaction. The practical outcome of the discussion so far has been the issuing of a circular by the Glasgow School Board, which, as it is an eminently common-sense document, may be commended to the attention of other boards. It is too long for quotation here in full, but we may say that it admits that "by far the greater portion of the work of education should be discharged within the school itself" and not at home. It directs that home-lessons should be given steadily throughout the year, and not specially before the annual inspection, and that they should be proportioned to the age of the scholar and his home opportunities for study. When a scholar is under several masters it is to be seen that the home work prescribed by any one of them is not excessive. A respite in the middle of the week is recommended, the suggestion being that the work for Wednesday evening be lighter than that for any other evening. No extra lessons are to be set for Friday evening. The detention of scholars after time-table hours, either as a punishment or for the preparation of lessons, is condemned. These regulations should have some effect in lessening what everyone admits to be an abuse, and one of the most serious evils connected with our present system of education. May it not be the case, however, that the secret of the matter lies deeper, in the principle on which the Education Act is framed—namely, the payment of masters by results? Under such a system it is not in human nature to resist the temptation to work scholars hard, and so to get as much as possible out of them.

THE ACTION OF MUSCARIN.

FRANZ HÖGYES, in a paper on the action of muscarin on the circulatory system, shows that muscarin lowers the functional activity of the central nervous system, and after a short time paralyzes it, whilst it at the same time slowly lowers the excitability of the peripheric nervous system. He demonstrates that the dilatation of the vessels after injection of the muscarin is an immediate consequence of the paralyzing action of this poison on the vaso-motor centre. At a later period there appears to be diminution in the excitability of the smooth muscular tissue of the body. Muscarin inhibits the action of the heart, because it lowers the excitability of the automatic nerve centres in the organ, and in fact abolishes it; and with this action it causes a gradual diminution in the excitability of the muscular tissue of the heart itself.

A SCIENTIFIC CENTENARIAN.

PERHAPS never in the history of science has a distinguished career equalled in its length that of M. Chevreul, whose name is best known in this country in connection with his investigations on color; and it is probably altogether unique for a *savant* to be able, at one of the most distinguished scientific Societies in the world, to refer to remarks which he made before the same Society more than seventy years previously. A few days ago M. Chevreul made a communication to the Académie des Sciences, and at its close he observed: "Moreover, gentlemen, the observation is not a new one to me. I had the honor to mention it here, at the meeting of the Académie des Sciences, on the 10th of May, 1812!"

TUBERCLE BACILLI IN THE URINE.

THE presence of the bacilli of tubercle in the pelvis of the kidney has been demonstrated in the dead body by Lichtheim, but they have not until now been found in the urine during life. Prof. Rosenstein, of Leyden, has described, in the *Centralblatt für die Med. Wissenschaften*, a case in which the bacilli were found in the urine in considerable numbers, and it is an instance in which the discovery is regarded as of diagnostic importance, since the symptoms of uro-genital tuberculosis were otherwise equivocal. The patient was a man thirty-seven years of age, of healthy family, previously of good health himself, who at the age of thirty-three began to suffer pain before and after micturition. During two years induration had been noticed, first in the right and afterwards in the left epididymis, which became enlarged until it attained the size of a small walnut. The testicles themselves were free. There was no enlargement of lymphatic glands, and no indication of lung disease could be discovered. The patient's general condition was good; the temperature normal. Micturition was frequent, a small quantity of urine only being passed each time; the whole amount in twenty-four hours varied between 800 and 1,660 cubic centimetres; the specific gravity was between 1,012 and 1,018; it contained much albumen, was acid, slightly turbid when passed, with small white flocculi in it, and the deposit was abundant, whitish-gray in color, consisting chiefly of pus-corpuscles with a little blood. The urine was investigated for bacteria in the following manner. It was received in a solution of thymol and allowed to stand; a small quantity of the sediment was then placed on a cover-glass, dried in the gas flame, and treated after Ehrlich's method, when it was found that the flocculi contained numerous tubercle bacilli. The observation is of much interest, but at the same time rather by way of suggestion than of proof. The question of the diagnostic value of tubercle bacilli is still in the region of probable rather than of certain knowledge. Much more work will have to be done before their presence in an isolated excretion can be accepted as absolute proof of a tubercular process. No surgical examination of the bladder appears in this case to have been made.

THE TREATMENT OF SNAKE-BITES.

AT a recent meeting of the Lower Rhenish Philosophical and Medical Association, held at Bonn, Professor Binz described an interesting series of experiments carried on under his direction, with a view of testing various antidotes to the poison of serpents. He remarked that numerous specifics are heard of amongst the native population of India, which, as a rule, are found to be of themselves inoperative. Professor Binz stated his opinion that when a real Indian poisonous snake has bitten a person in the usual manner, spirits can only serve to prevent or to alleviate the spasms of suffocation which are induced by the action of the poison on the respiratory nerves. Atropine and other specifics against imminent results of an analogous character, caused by narcotic influences, have been found ineffective against this deadly virus. The most favorable tests made were with chloride of lime, a filtered solution of which was injected into the same place where the fatal virus had previously been introduced. In seventeen trials, made in succession, the poisoned animal survived without the slightest disturbance of its healthy condition. In five succeeding experiments, when a relatively insufficient dose of the antidote was administered, or when animals suffering from disease were operated upon, the

chloride of lime served only to retard the fatal effects of the poison. The suggestion was made by Professor Binz that the adoption of this treatment in cases of the bites of dogs suffering from rabies might possibly be attended with favorable results, inasmuch as chloride of lime has been shown to have much greater power than any of the caustic substances now usually applied to dog-bites, which have been proved to be scarcely, if at all, effective against the consequences of snake-bites.

Correspondence.

"Audi alteram partem."

RHEUMATIC ENDOCARDITIS.

To the Editor of THE LANCET.

SIR—To one or two points in connection with the above subject, touched on in Dr. Sansom's Lettsomian Lectures, published in recent numbers of your journal, I would, with your leave, direct attention.

In speaking of rheumatic endocarditis, Dr. Sansom quotes and endorses the two practical reasons which I give for the failure of the salicyl compounds to control the cardiac, as they do the arthritic, inflammation: first, that the cardiac mischief has generally commenced before the patient comes under observation; and, second, that rest, which is so essential to the recovery of an inflamed organ, and which is easily got in a joint, is unattainable in the heart. The first reason makes prevention impossible, the second is a bar to successful treatment. But though this is true, it does not express the whole truth. That a joint generally recovers from rheumatic inflammation, and that the heart does not, is a statement which expresses the broad results of clinical experience, but expresses them in a manner which, from a pathological point of view, is bald and misleading. The truth is (and striking as the statement may appear, it is absolutely correct), that *everything which recovers in a joint recovers also in the heart*. The one structure in the heart which does not recover, the endocardium, is also the one which has no analogue in any of the structures of a joint. In studying the pathology and treatment of rheumatic endocarditis it is essential that this fact should be kept before us, for unless we do keep it in view we are sure to fall into error. The parts which suffer in a joint in acute rheumatism are the fibrous ligaments and tendons and the synovial membrane. The parts which suffer in the heart are the fibrous rings and valves, the endo and pericardial linings, and occasionally the muscular substance. The fibrous rings and valves are similar in nature and function to the fibrous structures of a joint. Each is apt to be the seat of rheumatic inflammation, and in both this inflammation is generally recovered from. The pericardium finds its analogue in the synovial membrane; each is a very vascular membrane; each secretes a lubricating fluid; and each has for its function the facilitating the movements of a solid body; each, too, is apt to be the seat of rheumatic inflammation; in each the inflammatory process tends to spread, and in both the tendency is to recovery. The endocardium has no analogue in a joint. There is nothing in a joint which bears the least resemblance to it, either anatomical or physiological. It is a non-vascular membrane, in which inflammation cannot, and, as a matter of fact, does not, spread. In nature

and function it is identical with the lining membrane of the bloodvessels, with which it is structurally continuous. When it is affected in acute rheumatism there is no general inflammation of its surface such as is found in the pericardium and synovial membranes; the mischief is limited to a small portion of one surface of the affected valve. I have elsewhere¹ shown that the occurrence of the lymph deposit which constitutes the endocardial lesion in acute rheumatism, and its limitation to one particular portion and surface of the valve, are to be explained, not by the direct action of the rheumatic poison on the endocardial lining, but by the mechanical rubbing against each other of valvular ligaments whose deeper fibrous structures are the seat of rheumatic inflammation and thickening. This thickening of their fibrous structure it is which makes the valves rub, and the rubbing it is which irritates and roughens the membrane which covers them externally. The inflammation and thickening of the fibrous structure of the valve may be recovered from. What is not recovered from is the roughening of, and lymph deposit on, its non-vascular and endocardial covering. This is not recovered from because the continued action of the valve keeps up the rubbing and mechanical irritation, and because the want of bloodvessels in the endocardium prevents absorption. This is a condition over which no drug could possibly exercise any control. It is directly of mechanical and only indirectly of rheumatic origin. But it is by no means certain that we may not in some cases, by the early and free administration of the salicyl compounds, prevent the inflammation and consequent thickening of the fibrous texture of the valve, which are the origin of all the mischief. If we see a case early, and give these compounds freely, we may prevent the heart from suffering as we undoubtedly do prevent joints from suffering. In no given case can we be sure of having got this result, for the absence of heart mischief can never be demonstrated to be due to the treatment. The possibility of such a result, however, is worth striving for, especially as the means of attaining it are also those called for in the interests of the joints. What is wanted is the speedy arrest of the rheumatic process. This object can be attained only by giving salicin or salicylate of soda in large and frequently repeated doses.

This leads me to remark that my recommendations in this respect have not been acted up to. Why I cannot say, for I have pressed the point over and over again. What I recommend is that from twenty to forty grains should be given every hour for six hours, or until pain is relieved (which it generally is within that time); that the same dose should then be given every two hours till the pain is gone and the temperature at or near the normal, which is generally the case within twenty-four hours. After that the same dose is given at widening intervals of three, four, and six hours for ten or twelve days. But instead of giving it thus freely and largely, most observers are content to give from fifteen to twenty grains every three or four hours. That is quite an inadequate dose, and not nearly enough to get the full curative effects of the drug. I would again, through your pages, urge the giving of the dose which I recommend. I do not exceed my right in asking that my treatment should be carried out in all its details before its results are subjected to criticism. Salicin is the preparation to which I give preference, not because I regard it as superior to salicy-

¹ On Rheumatism; its Nature, its Pathology, and its Successful Treatment, by T. J. MacLagan, M.D. London: Pickering & Co. 1881.

late of soda as an anti-rheumatic, but because it may be given in large and frequent doses without causing such disturbance of the system as not unfrequently follows the use of the salicylate, and necessitates its suspension. My experience, too, is that those treated by salicin (which is a bitter tonic) convalesce more rapidly than those treated by the salicylate. There is an impression abroad that it is very expensive. It is not so. Two of the chief English manufacturers of it have told me that they are prepared to supply it to hospitals and dispensaries at 10s. 6d. a pound. Convalescence is so much more rapid under its use that I am not sure it would not, in the long run, prove cheaper than salicylate of soda. But whichever is employed, let it be given in large and frequent doses. I make this appeal in the interest of the heart as well as of the joints. Let every case of acute rheumatism be regarded and treated as one in which heart complications may possibly be prevented, and it is probable that in some cases they will be prevented. But every hour is of importance; for it needs no argument to show that the danger to the heart is less in a case in which the course of the disease is arrested within twenty-four hours than it is in one in which three or four days are expended in the process. The fact has never been accepted by the profession that the course of acute rheumatism may in many cases be arrested within twenty-four hours of the time that treatment commences. The recognition of that fact is the key-stone to all possible success in the prevention of cardiac complications.

I am, Sir, your obedient servant,
T. J. MACLAGAN, M.D.

February, 1883.

POISONING BY STRAMONIUM.

To the Editor of THE LANCET.

SIR—Some time ago I reported to you a case on the above subject, in which the inhalation of chloroform was very successful.

Last week I was called to a boy, aged seven years, who had swallowed part of half a drachm of extract of belladonna six hours before. He had become drowsy at first, but was now wildly delirious, biting and kicking those who approached him. Mustard emetics had proved powerless, and the boy appeared to be getting worse. Thinking it now too late to employ emetics, I administered chloroform for about a quarter of an hour, and left the boy in a quiet slumber. On calling next morning I found my patient at play, and learned that he had awakened quite recovered, after a quiet sleep of seven and a half hours.

I am, Sir, yours truly,
ERNEST RAWSON, M.R.C.S.E., Etc.

Wellington, N.Z., Dec. 28th, 1882.

NEW YORK.

(From our Correspondent.)

I ATTENDED the special meeting of the Medical Society of the County of New York on the 29th ultimo, which was convened for the purpose of deciding whether the "New Code" adopted last year, which permits the allopathic physician to meet in consultation his brother of the homœopathic persuasion, should be cancelled or maintained. About 300 members were present, and every seat in the lecture hall of the College of Physicians was occupied. The special feature of the new code which was the subject for discussion was the following rule governing consultations:—

"Members of the Medical Society of the State of New York and of the Medical Societies in affiliation therewith may meet in consultation legally qualified practitioners of medicine. Emergencies may occur in which all restrictions should, in the judgment of the practitioner, yield to the demands of humanity." This clause of the new code, it may be observed, makes no reference to any particular school of medicine, and on the face of it presents no objectionable feature; that two legally qualified practitioners should meet in consultation appears perfectly justifiable and calls for no censure. To appreciate the full value of this clause it must be understood that the State of New York recognizes the existence of all the ultra schools of medicine, permits them to teach their several dogmas and to issue diplomas to those thus initiated as legally constituted medical practitioners. The State gives no special authority to any school of medicine, and thus no "regular" school exists. The allopathist, homœopath, eclectic, etc., all stand before the public authorized to practice by diplomas of equal value and importance before the law. As I understand the case, in England the law recognizes but one school of medicine, the regular allopathic system; this forms the only means of entrance into the profession. The barrier once passed, however, the holder of a diploma can take up with any system he may select, but a homœopathic diploma cannot be obtained. On the contrary, in the United States any half-dozen men can form themselves into a corporate body, and become possessed of the power to confer diplomas. They may teach anything they please, or can confer degrees without any instruction whatever, and their diploma is just as good as that issued by the College of Physicians of New York. All presenting the same credentials, the American public have gradually lost special faith in the so-called regular school of medicine, and have given a large share of their patronage to the holders of dogmatic views, homœopaths, eclectics, electricists, or otherwise. Much of this loss of confidence has been incurred by the regular school of medicine by reason of their granting diplomas to half-educated boys, who are daily thrust upon the public, armed with all the powers of physicians and surgeons, without the necessity of having attended or seen a single case, and in Massachusetts without the necessity of having studied an hour or passing any examination. It will therefore cause no surprise when I state that 157 medical practitioners voted to throw down the last frail barrier between themselves and the advertising quacks who rely on their own dogmas for public support. In vain such a man as Dr. Austin Flint, senior, raised his voice of warning, and reminded his hearers that under the old code the profession had prospered and become respected in the past; that those with whom consultations were now advocated constituted a body of men who held absurd dogmas, and who had organized themselves in opposition to the medical profession, taking a special name of their own, and practicing with exclusive dogmas, which ignored the accumulated experience of the past. No regular physician can fraternize with such men, said he, and maintain his self-respect. The eloquence of Dr. Flint was in vain. One member who was cheered expressed a wish to abolish all codes of ethics and claimed perfect freedom of action. Practically, the majority of those present were of the same opinion, and but sixty votes could be secured, from a list of nine hundred members, for the maintenance of the separate individuality of the regular allopathic medical profession.

To-day the State Medical Society, at Albany, confirmed the action of the County Society, and declined even to appoint a committee to investigate

and report in the matter. Thus, the medical profession of the State of New York have secured the freedom of action they desired, at the cost of being isolated from the American Medical Association, who will probably close their doors on the New York delegates at the next meeting, as they did at the last, for similar reasons.

I have endeavored to learn, what is called here, the true inwardness of this movement. It is a pretended concession to the outsiders of the medical profession. My own opinion is, that so far from being a concession, the movement is an aggressive one—a forward march on the enemy's camp. "This is no question of drugs," shouted Dr. St. John Roosa, at the New York meeting. "No," whispered a physician who sat on my right, "Dr. Roosa is right, it is a question of dollars and cents."

New York, Feb. 10th, 1883.

FIBRINOUS COAGULA IN THE RIGHT SIDE OF THE HEART AND PULMONARY ARTERY.

To the Editor of THE LANCET.

SIR—During my seven years' service in India in the Indian Medical Department, I came across several cases of the kind. I observed it to be the cause of early and unexpected death in pneumonia. At the commencement of the Afghan campaign in November, 1878, the 14th Sikhs were attacked with what seemed to be an epidemic of pneumonia of such severity as to necessitate the sending back of the regiment to India. The cause of death in many of these cases seemed to be the formation of ante-mortem coagula in the right side of the heart. In January, 1879, a case occurred among the Bengal Sappers and Miners, with whom I was doing duty at Jellalabad. The lung affection, of no great severity, had lasted above forty-eight hours, when word was brought to me that the man was dying. I found him suffering from distressing dyspnoea, for which all remedies proved unavailing. Having, with considerable difficulty, obtained a post-mortem examination, I found a firm coagulum filling the right ventricle and auricle, and extending "like the branches of a tree" into the subdivisions of the pulmonary artery.

I am, Sir, yours obediently,

H. MALLINS, M.B.,

Late Surgeon, Indian Medical Service.

Watson, February, 1883.

VEGETABLE *versus* ANIMAL DIET.

To the Editor of THE LANCET.

SIR—I forward you the result of an experiment I have just made. Last year about this time I determined to abolish fish, flesh, and fowl from my dietary, and see how I got on without them. I found at first that the ordinary vegetables, when eaten by themselves, were almost tasteless, and after a dinner consisting of them only I did not feel the satisfaction that I did after a meat meal. In the course of a few months my taste improved, and I learned to like them; and now I can eat them just as cooked. In the same way I have lost my taste for pickles, spices, pepper, and mustard; I still retain salt in small quantity. Now my meals satisfy me every way, and I do not experience the heaviness that I did after a meat meal. I used to suffer at one time from indigestion, but I have lost that since trying my experiment. I am very fond of mental work, and I find I can work better on my new diet. My bodily powers have not decreased, for I can run and walk as well as ever.

Alcoholic drinks I have lost a taste for, and even the smell in some cases is disagreeable; the same with tobacco. My bowels are as regular almost as clockwork. I was constipated once only for a month, and that was because I was travelling and could not well get whole meal bread. I was threatened with rheumatism, and had rheumatic pains in my joints, but all those have gone. My urine was very often loaded with lithates, but now it is always clear and never deposits any; this has been so since a fortnight after beginning. It smells sweet at times, and occasionally has a mild, roast meat odor. I have gained about seven pounds in weight during the year. My diet consists of brown bread, fruit, and a cup of coffee for breakfast. Two vegetables, brown bread, and a pudding or pie for my dinner. Tea consists of a cup of milk-and-water, brown bread, and jam. If I eat supper I take a little bread and water, or bread and jam, cold pudding, or boiled onions. I do not eat peas, beans, or lentils above once a month. I do not eat more food as a non-flesh eater than I did as a mixed feeder. Butter, cheese, eggs, and milk enter sparingly into my dietary. In the warm weather I eat more green stuff, and in autumn plenty of ripe fruit. My spirits are improved, and bad temper now rarely troubles me. My senses have increased in acuteness. I shall be pleased to give any information or willingly answer any queries. I am, Sir, yours, etc.,

T. R. ALLINSON, L.R.C.P. Ed.

Kingsland-road, E., Feb. 16th, 1883.

PERSISTENT HICCUGH.

To the Editor of THE LANCET.

SIR—Can any of your readers assist me in the treatment of the following case, which has already been seen in consultation by two other medical men of position?

Mr. S—, aged sixty-eight, in good health until last spring, when he had a sharp attack of bronchitis. In a few weeks he was at business again, and went on well until July, when hiccough set in, and from that time to this this troublesome complaint has continued. In December he again took bronchitis, and this disease now seems to alternate with the hiccough; but the latter is so distressing, and has exhausted my patient so much, that he is now in danger of death. I may mention that all the various functions of the body are normal, and he has not an ache or pain over and above the hiccough.

I have consulted all the latest authorities on this complaint, and I find it invariably treated as of little or no importance. I may mention that I have tried all the known anti-spasmodics, counter-irritation, firm pressure around waist, pressure on phrenic nerve, and galvanism; I have also tried quinine and arsenic in large doses, bromide of potassium, cannabis indica, etc. Every fresh remedy seems of service for a dose or two, but the complaint then returns with renewed vigor, and continues without a break for hours at a time.

I am, Sir, yours truly,

M. D.

January 31st, 1883.

AMPUTATION AT THE HIP-JOINT.

To the Editor of THE LANCET.

SIR—The Clinical Society, at its last meeting, did me the honor to give much of its time to the discussion of a method of amputation at the hip which I have devised. The personal element is unimportant, the mode of executing the largest operation on the body is very important. The operation I described, in *THE LANCET* first of all,

differs in momentous particulars from the continental methods which it is said to resemble. If the head of the bone be disengaged *first* and the vessels be divided *last*, at right angles, and *low* down in the thigh, the question of hæmorrhage is shorn of all anxiety. The operation has, within a brief period, almost supplanted the rough-and-ready flap method with its vast cut surfaces. It has already saved many lives in desperate cases where competent and impartial surgeons have held that no other treatment was possible. When the operation is said to be tedious, its steps have not been well considered. When it is rejected on the score of a few moments of time, there is something wanting in the surgical conscience.

I remain, Sir, your obedient servant,
FURNEAUX JORDAN.

Birmingham, Feb. 20th, 1883.

BEDSIDE URINARY TESTS.

To the Editor of THE LANCET.

SIR—Dr. Oliver has omitted to mention metaphosphoric acid as one of the tests for albumen. It was recommended by Dr. Grigg in 1880. A piece about the size of a split pea dropped into the urine in a test-tube affords, he says, on the application of gentle heat, a ready and certain test. As the acid dissolves, the albumen forms a white cloud around it. I am, Sir, your obedient servant,

F. P. ATKINSON.

Kingston-on-Thames, Feb. 7th, 1883.

IDIOSYCRASY IN FOOD.

To the Editor of THE LANCET.

SIR—I had the opportunity of witnessing the most interesting case of acute urticaria and spasmodic asthma I have ever seen the other evening whilst dining, showing how idiosyncrasy in certain articles of food affects certain individuals. A young lady was sitting at dinner, apparently in perfect health. She partook, amongst other things, of some rabbit, and in about ten minutes or so after she had eaten of it she was attacked with acute urticaria, showing large erythematous patches and wheals very prominent on the face and neck. She then was seized with violent attacks of spasmodic asthma, which obliged her to leave the table. I inquired if she had ever suffered this before, and she informed me she had after eating hare. I have seen several instances of urticaria, and one case in conjunction with spasmodic asthma, after eating hare, showing this peculiar idiosyncrasy in individuals to certain articles of food. I am, Sir, your obedient servant,

JAMES STARTIN.

Sackville-street, Piccadilly, Jan. 31st, 1883.

Medicus.—The payment of the fees should be insisted on. If erysipelas followed vaccination, *a fortiori* it would have followed small-pox, and probably in an aggravated form. Study the sequelæ of small-pox.

News Items, Medical Facts, &c.

"TRUTH THROUGH ERROR."—Under the above heading an American contemporary relates that a busy doctor sent in a certificate of death the other day, and accidentally signed his name in the space for "Cause of Death." The registrar says he wishes the profession would be as accurate generally.

GASTROTOMY IN THE SEVENTEENTH CENTURY.—The *Berliner Klinische Wochenschrift* of Feb. 12th contains a quaint account of a gastrotomy performed in the year 1635 at Königsberg. The subject was a countryman, who had six weeks previously swallowed a table knife seven inches long. Dr. Daniel Schwaben was the operator. He made an incision just below the left costal margin, exposed the stomach, and at once felt the knife; cut down upon it, and drew it out. The stomach wound at once contracted, and does not appear to have been sutured in any way. The wound in the belly-wall was sewn-up and dressed with a complicated array of balsams, lotions, and compresses, in which we may recognize a blind and imperfect antiseptic dressing. With the exception of hæmaturia, the man recovered without any troublesome symptom.

ARTIFICIAL HUMAN MILK.—The *Physician and Surgeon* says that Professor Frankland's method of preparation of artificial human milk is as follows: Let one-third of a pint of fresh cow's milk stand twelve hours, then remove the cream, and add to it two-thirds of a pint of new milk as fresh from the cow as possible. To that one-third of a pint of blue (or skim) milk left after taking away the cream, add a piece of rennet (about one square inch in size), which, after it has served its purpose, can be taken out and used daily for a month or two, and allow the vessel holding the skim milk to be placed in warm water, and there remain for from five to fifteen minutes, until curdling is affected. Break up the curd repeatedly, and carefully separate the whole of the whey, which should then be rapidly heated to boiling in a small tin pan, placed over a spirit or gas-lamp; during this heating a further quantity of casein (technically termed "fleetings") separates, and so straining after this, through fine muslin, is then required. Now dissolve one hundred and ten grains of powdered milk sugar in hot whey, and mix it with two-thirds of a pint of new milk as before prepared with extra cream. This gives one pint of artificial human milk, which should be used within twelve hours of its preparation. All vessels, and apparatus concerned in the manufacture must be kept scrupulously clean.

COUNTRY PRACTICE.

LUCKLESS he whom Fates urge on
To practice as a country surgeon,
To ride, regardless of the weather,
Encased in waterproof and leather;
And oft at two points diametric
Summoned to render aid obstetric,
Or sent for to a broken limb,
When Lady Blank, with nervous whim,
Or some imaginary fever,
Calls him a savage if he leave her.
A day and night in some lone cottage
He shares the lowly laborer's pottage,
And kicks his heels with wearied brain,
Yet watching o'er the wife's slow pain.
And that task over, happy he
If e'er he get's the well-earned fee.
Now comes the night; with toil oppressed,
Tired he seeks his place of rest.
Vain hope! his slumber is soon o'er,
Loud sounds the knocker at the door.
A farmer's wife, at nine miles' distance,
Needs his immediate assistance.
Grumbling and groping in the dark
To find the matches for a spark,
And, yawning as he heaves his breeches,
Envies his neighbor who hath riches. E.

Culstonian Lectures

ON

STERILITY IN WOMAN.

*Delivered in the Royal College of Physicians, London,
February, 1883.*

By J. MATTHEWS DUNCAN, M.D., F.R.C.P.L.,

Physician-Accoucheur and Lecturer on Midwifery at St. Bartholomew's Hospital, etc.

LECTURE I.

ITS NATURE AND AMOUNT.

MR. PRESIDENT, VICE-PRESIDENT, AND GENTLEMEN—Sterility is generally considered to imply the condition of woman who, under ordinary favorable circumstances for reproduction, does not bring forth a living and viable child. But the term is used with many other meanings, and I shall not state a definition, because I have no right or power to enforce adherence to it, and because, meantime, it is indispensable to have the word for various uses, and with the use of appropriate qualifying words ambiguity may be avoided.

Fecundity is a condition unique in gynecology in this respect—namely that it requires the combined matter and forces of two duly developed individuals to produce it. Sterility, therefore, may depend on error in one or in other, or in both.

The sterility of man as compared with that of woman is a simple matter. It depends on failure to produce semen, the production of semen more or less incomplete or imperfect, or of morbid semen (that is, semen conveying disease), or on failure to deposit the semen properly. With a view to investigation, the semen can be subjected to chemical and microscopical analysis, and the depositing organ can be examined and the conditions of deposition can be to a great extent ascertained. In woman the coördinate substances and functions are hidden and much more complex, and in her there are great organs and functions which have in the male no equivalent representative.

In the present lectures the sterility of man is not a subject for consideration, but one point in it cannot be passed over without some discussion and estimation—namely, its numerical amount. Much of our knowledge of the sterility of women

consists in numerical statements of amount under various circumstances, chiefly in marriages; and all such statements have a positive value for the physician, and still more for the political economist. But it is plain that, inquiring into the amount of sterility due not to unions but to women, we must exclude what is due to the male. Some good notion of the amount of this latter sterility is therefore indispensable.

Several investigators have attempted the solution of the question in recent times; but I refer only to the new work of Gross on Male Sterility. "It is not at all uncommon (says he) for physicians to assume that a man who is potent, and who is able to ejaculate, is capable of procreating. As a result of the omission to examine the emitted fluid, and carefully to explore the male organs, little is known of the relative frequency of sterility in the two sexes; and gynecologists, with the exception of those mentioned below, do not appear to have made any contributions to the solution of this important subject. I have been able (he continues) to collect one-hundred and ninety-two cases in which examination of both the husband and the wife demonstrated that the former was at fault in thirty-three, or in seventeen per cent. Of this number Manningham records one in thirty; Pajot seven in eighty; Mondot one in ten; Kehrer fourteen in forty; Courty one in ten; Noeggerath eight in fourteen; and I myself have found that the male was deficient in one example in eight. The cause of the sterility was azoospermism in thirty-one, and aspermatism in two. These facts show that the husband is at fault in about one case out of every six."

The matter is, however, still in a very insecure state, as may be shown by the statement of facts and considerations which must have important bearings on the question, but which have, so far as I know, been entirely neglected. Thus, it is assumed that by examination of the male and female we can decide whether one or other or both are at fault. Now, no doubt impediments or complete barriers to reproductiveness may be found in individuals of either sex; but in the great majority of cases of sterility no impediment or barrier can be discovered by the most careful and minute investigation; and this is verified by comparative observations in animals and in plants, wherein such inquiries can be carried to a completeness not attainable in the case of men and women. It is held that the man is not at fault if he duly ejaculates microscopically perfect semen, but this

is certainly not a warranted conclusion, as facts in human and comparative physiology, to be hereafter stated in these lectures, will show. In making estimates of male sterility, no account is taken of the fact that the faulty condition of a man's semen may be only temporary. It is forgotten that sterility may be due to faults in the semen, even though conception has taken place, and pregnancy been established; the foetus fading and dying prematurely from inscrutable causes, or being monstrous and not viable, or perishing from disease implanted in it by the male. It is forgotten that both parents may be simultaneously at fault, and this with or without discoverable cause, generally without discoverable cause.

Speaking of the sterility induced by domestication and that of hybridity, Darwin remarks that in both the sterility occurs in various degrees, and in both the male element is most liable to be affected, put sometimes the female more than the male. In another place, speaking of the liability of plants to be affected in their fertility by slightly changed conditions, he says it is the more remarkable, as the pollen, when once in process of formation, is not easily injured; a plant, he adds, may be transplanted, or a branch with flower-buds be cut off and placed in water, and the pollen will be matured. Pollen also, when once mature, may be kept for weeks, or even months. The female organs are more sensitive, for Gärtner found that dicotyledonous plants, when carefully removed so that they did not in the least flag, could seldom be fertilized; this occurred even with potted plants if the roots had grown out of the hole at the bottom.

Whatever may be the causes of sterility in women, there is a universally prevalent belief, which no investigations have shaken, that in the human species the paramount source of sterility is in the female. I know no scientific statement worthy of confidence as to the comparative influence of the two sexes; and the data of Gross, which I have quoted, contributing as they do towards the settlement of this question, are of importance and value in themselves, though they are far from substantiating the conclusion as to the amount of male sterility which he enunciates.

Of the sterility of women in whom, from gross and well-known causes, conception is impossible, these lectures take no account. Among such are cases of absence of uterus, and of imperforate vagina; conditions so rare that, in the present imperfect state of our knowledge, they do not affect statements as to women generally.

In describing sterility it is common to qualify it as absolute or as relative. No author on human sterility uses the term, without qualification, as including relative sterility. But when used without qualification it includes at least absolute sterility.

Absolute sterility, sometimes called congenital, including all cases where there is no child, no miscarriage, no abortion, however early, comprises two sets; first, those where there is no conception, and, second, those where the impregnated ovum disappears in the tube or in the uterus without leading to what is recognizable as an early abortion. Some cases of women aborting every month are known; there is discharge of a highly developed decidua vera every four weeks, and there may be no trace of an ovum in it; and this monthly discharge is arrested by suspension of cohabitation. But there may be many abortions earlier than this without these conditions, and of such practically nothing is known; they are classed along with those cases of absolute sterility where it is supposed that no conception takes place. In cases where there is no conception there may be no possibility of conception from the failure of

the ovary to prepare and mature an ovum. These varieties of absolute sterility are well illustrated and easily made out in the history of animals, and still more of plants.

Sterility, not absolute, implies the failure to produce a viable child, while there may be evidence of conception—that is, of the commencement of the production of an embryo. A woman may be sterile because the ovum perishes in utero or becomes unnaturally developed, as in myxoma of the chorion and some monsters; and this premature death or unnatural production may be owing to ovuline imperfections derived from the male or from the female. A woman may be sterile because the womb does not afford to the ovum due accommodation, or nourishment, or neither; or because the womb ejects it prematurely from its cavity; and these unnatural conditions and events may arise from either local or constitutional causes.

In absolute sterility and in sterility not absolute there is no production of a viable child, no addition made to the population; and all such sterility is sometimes, especially by economists, considered absolute; for indeed, in the point of view of population, it is so. But it appears to me desirable to restrict the term absolute sterility to those cases where there is no evidence even of conception. Sterility indicates a larger group, including that of absolute sterility, and all those other cases where no addition is made to the population.

There is another great department of sterility no less important than the kinds just mentioned, where a woman may produce one or even several living children, but, in number, not according to her conditions of age and length of married life. This is called relative or acquired sterility. The gardener may have a plant, producing not a single flower, absolutely sterile; or producing flowers, and setting seeds, but bringing none to maturity, or if to maturity not to perfection—a sterile plant which cannot continue its species; but he may also have a plant which produces flowers and matures perfect fruit, but in such small number as not to save it from the charge of sterility; and this is relative sterility. In woman it is often seen in cases of production of a single child—an only child sterility, if such a seeming contradiction in terms can be permitted, of which we often hear. A woman may be relatively sterile from producing, according to her age, only a small number of children with ordinary intervals between successive births, or from the number being rendered small by the extraordinary delay or loss of time between successive births, and in other ways.

All kinds of sterility may be congenital or may be acquired. It is therefore undesirable to use these terms as indicative of distinctions. For instance, an absolutely sterile woman, one who never conceives, may be so not merely from congenital causes, but also from disease acquired in advanced life; or, again, a relatively sterile woman may be so, not from an acquired cause, but from conditions which were congenital in her.

The amount of sterility in women (including the relative kind) is found by counting the number of productive and of unproductive marriages of women within the reproductive age, or from fifteen to forty-five. Lever, giving no numerical details, says that 5 per cent. of married women are wholly unprolific. West found the average of sterile marriages among his patients at St. Bartholomew's Hospital to be 1 in every 8.5. Hedin, a Swedish minister, noticed that in his parish of 800 souls one barren woman is not met with for ten fertile. Frank and Burdach roughly state that only one marriage in fifty is unproductive. Simpson made an inquiry into the sterility of married women in Grangemouth and Bathgate. Of 210 marriages in

Grangemouth 182 had offspring; 27 had none; or about 1 marriage in 10 was without issue. Of the 27 unproductive marriages all the subjects had lived in wedlock upwards of five years, and in all the female had been married that period before she reached the age of forty-five. Of 402 marriages in Bathgate 365 had offspring; 37 had none; or about 1 marriage in 11 was unproductive. There was at the same time living in the village 122 relicts of marriages, and of these 102 were mothers; 20 were not mothers; or about 1 in 6 had no family. In all, of 467 wives and widows 410 had offspring; 57 had none; or about 1 marriage in 8 was unproductive. Of these last 57, 6 had not been five years married, and there were other 6 above the age of forty-five when married. If we subtract these 12 we have of 455 marriages 410 productive, 45 unproductive, or 1 in 10.1-9 without issue. Simpson found that among 495 marriages of British peers which had lasted five years or more, and in which the husbands were under fifty-seven years of age, 81 were unproductive, or 1 in 6.1-9. Ansell found that among 1,919 marriages of spinsters in the upper classes at an average age of twenty-five years, and not counting as childless those who had merely stillborn children, there were 152 without issue, or 8 per cent., or nearly 1 in 12. In this collection all the parents survived the childbearing age, and he considered that there was no further chance of childbearing if the female was

Over 48 and had had no child for 2 years.

" 47	"	" 3	"
" 46	"	" 4	"
" 45	"	" 6	"
" 44	"	" 8	"

Under 44 " " 10 "

I have taken the registers of Edinburgh and Glasgow for 1855, and have found the number of first living children in that year. With this I compare the number of marriages in that year. It is evident that the number of first children only should be counted, for they indicate all the wives who are not sterile. If one living child is born to a marriage, that marriage is not sterile. Further, it is evident that, although the first births in 1855 will not all pertain to the women married in that year, it may be assumed that if the marriages be nearly the same in number for a few contiguous years, the first births in one year will give the fertility very accurately of any of the contiguous years. From this fertility the sterility can be easily computed. Now in 1855 there were, in Edinburgh and Glasgow, 4,447 marriages, and 3,722 first deliveries of living children, leaving 725 marriages sterile, or 1 in 6.1. But in these figures are included 75 marriages which did not take place till after the women had passed forty-four years of age, and these will damage the physiological value of the statement, as these 75 women could not be expected to be fecund. Of women between the ages of fifteen and forty-four inclusive there were married 4,372; among women of the same ages 3,710 had first living children, leaving 662 marriages sterile, or 1 in 6.6. In other words, 15 per cent. of all the marriages between fifteen and forty-four years of age, as they occur in our population, are sterile. But this final estimate from the Edinburgh and Glasgow data has to be corrected for the dead born, these being not counted.

We have thus fairly good statements of the amount of sterility which are not very different from one another:—

Patients in St. Bartholomew's Hospital	1 in 8
Inhabitants of Grangemouth	1 in 10
Inhabitants of Bathgate	1 in 10
British peers	1 in 6.1-9
Upper classes (Ansell)	1 in 12
Inhabitants of Edinburgh and Glasgow	1 in 7

Omitting that of British peers, the highest estimate is the last, and it is probably the only one in which living children are used, to the exclusion of dead, as the index of fecundity. Were dead children included, there would be a great reduction—at least 4 per cent. The lowest estimate of sterility is that of Ansell. In it a woman having a stillborn child is held as fertile, and the women are the very best in the community, those living in easy circumstances and making use of the protection of life insurance; were it otherwise, the estimate of sterility would no doubt be higher. We have thus estimates of sterility varying from 1 in 7 to 1 in 12, and may have considerable confidence in laying down 1 in 10 as very nearly the true amount.

I know no estimate of those who are absolutely sterile—that is, who do not conceive, or who, if they do conceive, give birth to not even an abortion. But there are a large number in the better classes, for within the last five years there have consulted me at my house, mostly on account of sterility, 504 absolutely sterile women, married between the ages of fifteen and forty-five, and of these 337 were more than three years married. Though this shows a large number in existence, it gives no ground for an estimate of frequency among the married. The following table gives a classification of these 504 married and absolutely sterile women, according to age at marriage and number of years married:—

TABLE I.
Case-book Table of Sterility.

Age at Marriage.	Years Married.							Totals.
	Und. 3.	4 to 8.	9 to 13.	14 to 18.	19 to 23.	24 to 28.	29.	
15-19	12	19	15	4	7	2	1	60
20-24	70	66	37	24	13	9	—	219
25-29	47	51	20	8	8	—	—	134
30-34	26	20	8	4	1	—	—	59
35-39	6	13	4	—	—	—	—	23
40-45	6	3	—	—	—	—	—	9
Totals...	167	172	84	40	29	11	1	504

It is certain that all populations are relatively sterile; and the economist makes many estimates, such as the deficiency of offspring of the actual marriages, or the deficiency of the actual births below what they might have been had all the women in the population been married at the most favorable time for childbearing. The solution of these and similar questions is an object of greater interest to the statesman than to the physician. They demand, for their solution, much calculation, and need not be entered on here.

The degree or amount of relative sterility of the average individual varies, of course, according to the age at marriage, and it is not to be estimated by the deficiency below what is possible in childbearing, but below the average amount of fertility in marriages at the various ages, or below what is not excessive, what can be done without injury to the average mother's health.

The average individual woman must be found and considered, for individuals vary extremely. It is not a rare observation, and I have one before me where the easy birth of a single child exhausted the fecundity of a healthy woman of twenty-five years of age at the time of the birth, and completely ruined her general health during the remaining childbearing period of life. This woman was examined by many physicians, and all concurred in finding no cause of the weakness and inability but the childbearing. On the other

hand, Ansell records the case of a woman married at twenty-one, who in twenty-seven years gave birth to twenty-five children who all reached adult age, and the mother died of old age at eighty-eight.

Only-child fertility or one-child relative sterility occurs in two forms; as an exhaustion of the fertile energies leaving the general bodily health vigorous, or as an exhaustion of both sexual power and general constitutional strength. It is a relative sterility which is familiar to the public from its frequency and its importance in social respects. Ansell, in 1,767 fertile marriages, with a mean age at marriage of about twenty-five years, and allowing ample time for the exhibition of fecundity, as we have already stated, found 131 cases of one-child relative sterility, or 1 in every 13 fertile marriages. The degree of this relative sterility may be approximated by comparing it with the average fertility of the same women, which was nearly 6; or, in other terms, the relative sterility of these 131 only-child fertile women was 655. Instead of having 131 children, they would have had 786 children if they had even reached the average fertility of their 1,636 sisters, and they would have had still more if they had reached a normal fertility instead of this average fertility, meaning by normal fertility what they might have had without injury to health, judging them by other women.

There are several tests of relative sterility secondary to that implied in the paramount question, How many did she bear? These subsidiary tests are based on the ascertained course of natural fertility, and show the deviations from this course of the relatively sterile. Inquiry made by these tests implies a knowledge of how many children a woman will naturally bear, or is likely to bear, and of the natural order of births. They are as follows:—

1. When after marriage did she begin the career of childbearing? 2. How rapidly did the children follow one another? or, what was the interval between successive births? 3. When did childbearing cease? or, what was the age at the birth of the last child? 4. How long was the childbearing period of life? or, what was the interval between the beginning of the first pregnancy and the end of the last?

In studying population, these subsidiary matters are little regarded, for the statesman has direct interest only in the mutually related questions, How many are born? How many might have been born? What is the health of those born? The answers to these inquiries give him the actual relative sterility of the population, and in the case of a population this includes the absolute sterility. He may now attempt to increase or diminish the sterility of the people, not neglecting the health of the progeny, so far as it is related to fertility; and this control he will effect by raising or lowering the age at marriage. On the other hand, the physician, having care of individuals, not of a people, and advising each from year to year of life, has his chief interest in these subsidiary matters, which the statesman may not utterly neglect, but may leave to the care of the medical philosopher.

The importance of the question, How soon after marriage does a woman bear her first child? is self-evident, and it will be found to be more a test of sterility than it appears at first sight to be. Whitehead, founding on the observation of 541 married women of the average age of twenty-two years, makes the average interval between marriage and the birth of a first child to be eleven months and a half. Sadler says that married females do not become fruitful, on the average, during the first year of their nuptials, but nearly so. A great number of cases, he says, which he

has collected, with a view of determining this point, gives three-fourths of them as producing their first child at the average of one year after marriage.

From the Edinburgh and Glasgow registers for 1855 I was able to make out this point in 3,722 cases. But in these extracts from the register there are two sources of error, which prevent an exact comparison with the results of Ansell's more valuable table, for twins are excluded, being placed in the column of secundiparae, not of primiparae. (See Table II.) And, still more important, the great number of mother's whose children were stillborn is excluded. Now, twins affect specially young, immature, and quickly breeding mothers; their omission, therefore, from the column of primiparae will tend to delay the estimated time of primiparity. Again, a similar delay will result from the omission of women having dead children from the primiparous column, for such women, when they bear a first living child, which may be in reality a second, third, or other child, will appear in the primiparous column with an over-estimated and erroneous retardation of primiparity.

The Edinburgh and Glasgow table gives a mean interval of about seventeen months between the marriage and the birth of a living child. It shows that fecundity is not demonstrated by a living child in the majority of cases till a year of married life has passed; nearly two-thirds of the whole beginning their families in the course of the second year of marriage. It also shows that there is no ground for presumption of sterility till the fourth year of married life is entered upon; for while of those three years married and less than four 133 bore a first living child, there were only 154 who did so in all the subsequent years taken together. Of the whole 3,722 only about one twenty-fourth part began bearing living children after four years of married life had elapsed.

Ansell's table includes first stillborn children, and is corrected for twins, and gives us the data in 6,035 cases. It is therefore better than the preceding, and better than any other of which I know regarding this point.

Ansell's table gives a mean interval of nearly

sixteen months between marriage and the birth of a child. The majority of the women in Ansell's table bore their first children before the first year of married life had elapsed—nearly seven-eighths before the expiry of two years of married life. It also shows that there is no good presumption of sterility till the fourth year of married life is entered upon; for while of those three years married and less than four 421 bore a first child, there were only 292 who did so in all the subsequent years taken together. Of the whole 6,035, only about 1-21st part began bearing children after the third year of married life, and only 1-39th part after the fourth year.

It may therefore be held that married women delaying the commencement of fertility beyond sixteen months are already exhibiting a degree of relative sterility; and this conclusion is quite in keeping with the rest of our knowledge of this subject.

The second question proposed is, How rapidly do the children in a family follow one another? or, What is the interval between the births of successive children? Great authors on population used to hold that breeding women never exceeded, in rate of prolificness, a child every two years; but, like many of the other principles on which Malthus and the rest based their theories, this has proved to be false. With our present knowledge, we can assert that Malthus erroneously endowed woman-kind with a degree of relative sterility; for women who breed do so at an average rate of a child every eighteen months, or nearly so.

I here give a table compiled from the Edinburgh and Glasgow registers, which makes the average interval between successive children nearly twenty months. But this requires several corrections, which will, on the whole, tend greatly to reduce the amount. Twins are included, and counted as two children. But a source of greater error is the exclusion of dead children, whether one or more. This last error might not be grave, or even an error at all, in the view of an economist such as Malthus; but reckoning for it would make his actual error comparatively much greater. Table IV., like Table V., made up from Ansell, is not

18th "	23.02 "	15.0 "

Ansell's table does not require correction for twins or for dead-born children, and its value may be judged by the statement, indefinite though it is, that it is based on more than 25,000 observations. The average interval, as calculated from them, is eighteen months. Ansell's table may be studied, further, with a view to a statement of the average interval in those who have not excessive families, but families of natural or normal number. For those mothers who have shown excessive intensity of fertility, either by a high number of births or by excessive rapidity so long as childbearing continued, are mixed up in each successive row of figures with those that are normal, or nearly so. Now, looking at the rows of figures of families varying from four to ten, which show intervals of twenty to twenty-one months, we are safe in stating the average interval for normal families as above twenty months, yet, probably, considerably under two years.

It may therefore be held that a married woman who, during childbearing life, does not have a child every twenty months is exhibiting relative sterility.

The third question is, When did childbearing cease? or, What was the age at the birth of the last child? Now, it is the rule to confuse the childbearing period of life with the period during which a woman menstruates, and this is a great mistake. It is only a part of this that, in married life, is occupied by childbearing, except in rarest cases, such as have never come under my observation. When a woman begins childbearing she generally, under favorable circumstances, continues her career of fertility steadily till her last child is born.

The registers tell us when women actually begin to have children, and I have already made use of such information, but we have no data nearly sufficient to decide what is the average age of commencing fertility; we may, however, be sure, from what we do know, that it is not the age of puberty or of commencing menstruation, and that it is not the age of nubility or age at which procreation is

commenced with the greatest advantage to mother and progeny. It is evidence of good conduct in the race that we cannot get sufficient data, there being very few unions permitted in early life. The great mass of our women are, fortunately, married within the limits of nubility, or the marriageable age. Nevertheless, it is very desirable that we should find out what is the mean age of commencing childbearing.

Regarding the time of cessation of childbearing we have more exact information, and it shows well the distinction that must be made between the cessation of menstruation and the cessation of procreation. Menstruation ceases at from forty-five to fifty years of age, but childbearing ceases at an average age of thirty-eight. This cessation arises from no imperfection or decay of organs, that has been demonstrated, but it may be due to that nevertheless. It is highly probable that its main cause is a cessation of functional vigor or activity, for it is delayed in women who have begun their fertility late in life.

On the subject of the cessation of childbearing our best information is derived from Ansell, whose calculations are based on 4,899 observations, restricted to those in which both the father and mother survived the childbearing age of the latter, a point which was determined as regards each case in accordance with a scale already given, whose chief governing rule is not to suppose a woman under forty-four years of age to have borne her last child until she has been for ten years barren. The quinquenniad 39-43 is that at which the largest number ceased to bear children. Thirty-eight years is the mean age of mothers, married at the mean age of twenty-five, at the date of the birth of their last children in cases where childbearing was not prematurely terminated by the death of either parent.

The productive period begins earlier, and it is protracted to a later age, in cases where the children are numerous than where they are few. This protraction is shown by the following table:—

TABLE VI. (from Ansell.)

Showing the Mean Age of Mothers at the Birth of their last Child in Families of different numbers.

Number in family.	Mean age of mothers.
1	31.08
2 or 3	34.21
4 or 5	37.04
6 or 7	39.21

10, 11, or 12	41.74
13, 14, or 15	42.83
16 or more	44.32

Women have, in their career, and with a view to our present subject, many stages in life. There is the age of puberty or of commencing menstruation, and this is to be distinguished from the age of commencing childbearing, regarding which we have no data adequate for a decision. But the age of commencing childbearing, though it may be identical with that of commencing menstruation in individual cases, is certainly not nearly so in the mass of women, being fortunately considerably delayed. Then, after the age of commencing childbearing comes the age of nubility or marriageable age, that at which a woman can enter on married life with the best chances of having a healthy and not excessive family. After the age of nubility comes the age of cessation of childbearing, which, as already said, is thirty-eight for women married at twenty-five years of age. A woman may bear children after this age, or even after the cessation of menstruation, but such cases

are exceptional and rare. The last stage in their career is usually the cessation of menstruation at an age of forty-five to fifty.

There is a mean age of puberty and of commencement of possible procreation, a still further advanced mean of commencing procreation, a still further advanced mean of nubility or fitness for procreation, a still further advanced mean of cessation of procreation, and lastly comes the mean of cessation of menstruation and of possible procreation. Most of these stages of woman's life have their analogues in the female life of the lower animals which are best known to us, and some of them have analogues in the life-history of plants. There can be no doubt that they all have their coördinate physical states of the genital organs, and in this department there has been much successful anatomical investigation, especially as regards puberty, nubility, and the cessation of menstruation.

Writing regarding the age of cessation of childbearing, Whitehead makes the following pertinent remarks: "The sum of the ages of the individuals (38) recorded in the preceding table, at the time of their last delivery is 1,586, giving an average of 41.73 years; the average age of the same individuals, at the time of their last menstruation, is 47.54 years; so that a period of nearly six years is here indicated, during which, although the menstrual function continued to be more or less efficiently discharged, and the health good, aptitude for procreation did not exist. They were all placed under equally favorable circumstances for the continuance of childbearing so far as regarded their matrimonial position. . . . A like period of uterine quiescence," he adds, "is observed before childbearing begins."

The average cessation of childbearing is for all women no doubt between thirty-five and forty years of age, and a woman in whom this career ceases earlier shows relative sterility.

To the question, How long does childbearing continue? it is easy to give some answer; for if the average age at the commencement of childbearing is twenty-six years, and the mean age at termination is thirty-eight, the average duration of childbearing is twelve years. The duration of fertility will be the number of pregnancies multiplied by nine (months) added to the number of intervals multiplied by nine (months). It will vary therefore from a case of one-child sterility, with nine months of the childbearing period of life, to a case of ten-child fertility, with a childbearing period of life of 171 months, or about fourteen years; and to a case of twenty-child fertility, with very much less than thirty years of childbearing life; very much less, because women of this great and excessive prolificness do hurry their children into the world to get through the high number.

From Ansell's table of 4,899 married women, whose ages at the birth of their last children were known, and where both parents survived the childbearing age of the mother, I have constructed the following table to show the nearest figures I can give to the actual lengths of childbearing life in families of different members. The commencement of childbearing at twenty-six years of age is, in all cases, assumed, because it really was very nearly the mean age in Ansell's collection.

Table VII. affords us further valuable information as to the duration of childbearing in families which reach the normal limit of about ten, and we see that it is about fifteen years. A woman then may be regarded as relatively sterile who, married within the years of nubility (about 20-25), ceases to have children within fifteen years from the birth of her first child.

We must now try to answer the last and compre-

hensive question, How many children does a woman bear? On the answer to this depends the settlement of the amount of relative sterility. It cannot be satisfactorily answered directly, on account of the paucity of data, but such answer as we can give is corroborated by the various subsidiary answers which we have just furnished. We shall not enter on subjects important politically, such as the numbers in actual families, the number to a marriage, etc., because these are foreign to our present inquiry.

In the district of St. George's-in-the-East the Statistical Society found, among the poorer classes, eighty mothers who had been married at ages varying from fifteen to nineteen, and who had lived in wedlock at least thirty-one years, or all the childbearing period of life. These fertile wives had borne on an average 9.12 children. Considering the undoubted existence of evident sources of error, all tending to unduly diminish the average amount of fertility, we may safely say, using the data of St. George's-in-the-East, that ten is about the average fertility of fertile marriages lasting during the whole childbearing period of life. The average age of marriage in England is twenty-five, and consequently the production should be less than ten, the women living in fruitful wedlock from twenty-five till the end of the childbearing period of life, not all the childbearing period.

TABLE VII. (from Ansell.)

Showing the Average Age at Cessation of Childbearing in Families of different numbers, and the Time occupied in Childbearing, estimated at the rate of eighteen months for each child, in families of less than ten children: the mean age of mothers at commencement of childbearing being twenty-six years, and the parents both surviving the childbearing age of the mother according to the scale of Ansell (p. 50).

Number of family.	Number of cases.	Mean age of mothers.	Time occupied in childbearing.
1	244	30 years & 6 months.	1 year & 6 months.

14	43	41 " 10 "	15 " 10 "
15	34	42 " 8 "	16 " 8 "
16	10	43 " 6 "	17 " 6 "
17	10	43 " 5 "	17 " 5 "
18	6	44 " 7 "	18 " 7 "
19	1	45 " — "	19 " — "
20	1	45 " — "	19 " — "

The actual fertility of fertile marriages in England, if only nine in ten wives have living children, is, according to Farr, 5.2; but with a view to contrast with the data of St. George's-in-the-East and of Ansell this figure needs correction; for in making it up, the condition of living in wedlock till the end of the childbearing period of life is omitted. If that condition were not omitted, there would of course be a large increase of fertility of wives in England. Ansell's collection includes

1,767 spinsters married to bachelors at a mean age of twenty-five, and living in fruitful wedlock till the end of childbearing, as calculated by a scale already given, and the production was 5.7, or nearly 6, a figure which I regard as indicating a less fertility than that of Englishwomen generally.

The fertile wives of England, without the condition of persistency in married life till the end of the childbearing period of life, bore 5.2 children. Ansell's mothers in the upper classes, married at a mean age of twenty-five, and living in wedlock till the childbearing period of life was passed, bore on an average 6 children. The fertile wives of St. George's-in-the-East, a poor class, living in wedlock all the childbearing period of life, bore above 9 children. Each of these statements yields some corroboration of the others; and, keeping in view some further evidence, they seem to justify us in holding that a healthy woman, living in wedlock all her childbearing life, under the most favorable circumstances for natural procreation, should have a family of 10; or women, under such circumstances, bearing fewer than 10 are relatively sterile, and the sterility is inversely as the number. Further evidence to the same effect is got by referring to the data derived from the registers of Edinburgh and Glasgow for 1855. There (Fecundity, p. 125, 2nd ed.) I found that, in fertile wives married at various ages, there was a fertility of between seven and eight after the lapse of fifteen years of marriage, counting to the birth of the last child; and fifteen years is full allowance for persistence in fertility. Now, as many women are married some years after the best period for commencing childbearing, we may, by making allowance for such delay, raise the number from between seven and eight to ten.

There are many women who bear families above ten in number, and it is desirable to devote to them further special consideration. Such families are, on the whole, abnormal or excessive. For

TABLE VIII.

14	11	—	—	—
15	6	1	16.66	6

many an individual woman a family less than ten is excessive. We have, indeed, spoken of the occasional calamitous character of only-child fertility. But there is a mass of evidence tending to show that a family, in the average female, rising above ten, begins to be excessive and increasingly so as the figure increases. It may seem paradoxical to bring the consideration of excessive families into a lecture on sterility, but in the next

lecture the paradoxical character of this proceeding will disappear.

The bearing of a first child is well known to be very dangerous, often fatal to the mother. After this she comes into a period of childbearing which is the safest, and which continues while she has a natural or ordinary degree of fertility. The danger of primiparity is, for a fertile woman, inevitable, but the special danger of multiparity is incurred only when a family is excessive; and I hold this danger to be good evidence (along with other) of excessiveness. It is, at the same time, to be kept in mind that danger has been demonstrated to rise with increasing elderliness; but elderliness of the mother is an essential element in a question of excessive family. I extract from my work on Fecundity, etc., Table VIII., whose composition is there stated. It does not give actual mortalities, but only such mortalities as may be compared with one another with a view to making out the peril attending confinements of different numbers.

In the sequel I shall give further and varied evidence as to the excessiveness of families above ten. This evidence is based not on the danger to the mothers only, but on the nature of the production—that is, on the occurrence of twins, of weakly children, and of idiots.

Croonian Lectures

ON

MODERN THEORIES AND TREATMENT OF PHTHISIS.

Delivered at the Royal College of Physicians, London,

By JAMES EDWARD POLLOCK, M.D.,

Consulting Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

LECTURE I.

MR. PRESIDENT AND GENTLEMEN—When your kindness committed to me the charge of laying before you in these lectures some subject of more than passing interest to our practical profession, I had to consider whether I should attempt an addition to the knowledge we already possess, or taking the standpoint of critical experience, and placing you upon it, I might not with more advantage review the labors of others, and the ever-varying feature of opinion. In the former case I should have been able to add but little to the great mass of knowledge contributed by many observers, and by several whom I see before me, whereas in the latter I should but make an appeal to the experience and judgment of all, and if fortunate might not only give expression to the doubts and difficulties of some, but possibly afford more firm ground for conclusions on subjects of grave import to every practitioner of our art. This method of reviewing and taking stock of our knowledge has much to recommend it, provided it be not too frequently practiced. There are transition periods in which it is a wise, almost a necessary, act of mental impartiality to look back and see both what has been *done* and *thought* by our predecessors. There is a natural proneness to a belief in the superiority of our own views to those who have gone before us. We are in fact their critics, and the critic always fancies himself higher than the criticised. We are the inheritors of their labors and their intellectual accumulations, and our first step as heirs is to value at what we think a just estimate the legacy of their knowledge. Of course every student has to place himself on a

level with the past of that branch of Science or Art which he proposes to acquire; but every impartial critic has not only to know what has been observed and thought, but should study the causes which led up to the various opinions which he will find recorded. The art of which we are ourselves students is essentially transitional; it has derived its form and color from the errors as well as the wisdom of past generations, while occasional great leaders have stamped upon it the impress of their own genius and individuality. To see with any degree of clearness, as the great observers of the profession saw one or more generations back, we should, like them, emerge from the comparative darkness of the age in which they lived, and from the mists of false teaching and imperfect science in which they were trained, into the light which emanated from their own genius. Around everyone who has added something real to knowledge, there is a luminous atmosphere which enables him to see what others did not recognize, and to us living in the far distance of time, it is not always easy to distinguish this increased illumination shed by genius from the more steady light of gradually increasing knowledge. What I mean is that the discoverer and propounder of a new theory or observations tending to reverse the opinions of the time is surrounded by a halo, into the zone of which we may scarcely enter, but which largely affected the results of his teaching at the time. Our medical knowledge, but especially our medical theories, have, as we know, received the impress of many a great name, and as successive generations continued to teach these doctrines the whole community of the profession became impregnated with the views of certain great masters. The advance of medical knowledge has ever been, as is indeed the case with all the sciences, a record of the work of many observers and laborers, but illuminated here and there by the genius of a few who from time to time stood out from the crowd generalizing the knowledge and opinions of the many, and thus became the representative of theories which were to bear their name, and give form and color to the knowledge of the day. It is, indeed, well for us that our art is transitional, and that we hold to no teaching which can be disproved, but these masters did a good work in crystalizing and so transmitting definite propositions for our reception or refusal.

Now, it is because our knowledge is essentially transitional and progressive that I venture to think I may occupy your time not unfruitfully in reviewing some of the changes of opinion through which we have passed, and are passing. I believe that we are now exactly in one of those periods of thought when some think that all old things are passing away, and "that all things must become new before we are nearer truth." I believe that the wisdom of past observers, which is only a synonym for their knowledge, is being slighted because it is old, and that the *eureka* of modern observers and theorists threatens to disturb much that is venerable, not alone from its age, but from its deep foundation in truth. I see in much of the present day a tendency to generalize from a few facts instead of accumulating great stores of evidence from which to deduce something like a general law. We cannot but recognize a tendency to refer all morbid influences to a few observed microscopical objects in diseased matter, and from these to rush to a conclusion affecting the very roots of our social life that all such matter is transferable, and may be propagated from individual to individual. Much that was believed—nay, much which was proved—is brought up into the focus of argument, where theories are sometimes more prevalent than facts. We are almost asked to believe

that all diseases have a common nucleus. In the midst of our modern light a disbelief has crept in of ancient lights, which, not the less, "were lights shining in darkness."

It may be that the tendency of the hour is not to incredulity, indeed it is rather to an over-advanced faith in some things, but it is shaky on some ascertained points, and, as all young life, is mixed with imaginative speculations which tend to error. We have discovered some things, and much that is great and useful; we can prevent germs of disease from entering the system; we can prevent secondary infections, but it does not follow that all disease is of germ origin or that all secondary disorders are from septicæmic sources. We have by careful pathological work made it clear that many broken-down lungs have never had a trace of tubercle, while that many tubercular deposits have never broken up the lung structures, yet it does not follow that every case of phthisis is of inflammatory origin, or that innumerable cases do not progress from tubercle to caseation and softening and cavity with their known train of events. The contagiousness and inoculability of phthisis are now the received faith of many, and the treatment proposed has of course varied with the theory of the proposer. Some are sent to snowy heights, others to relaxing river beds. Disinfectants and antiseptic remedies are more in vogue than nutrients, and surgical principles are applied to cavities in the lung. I mention these not to disparage them, but to justify my assertion that we are actually in one of those transitional periods when thought is rife on the subject of phthisis, its cause and its extirpation. In the days, Sir, when you and I were students we found it difficult to get a word spoken about phthisis. It slew then, as it slays now, about one-fifth of the adult population, but few lecturers spoke of it, and no student was examined on it. We never asked then if hæmoptysis were a cause or a consequence of any of the other events of phthisis; of the nature of its peculiar fever and waste; of the cause of its secondary disorders; of the retarding structural alterations which nature erects as barriers against its local mischief. But those have become subjects of investigation, and inquiry is awake, and good, and not evil, must be the result. There is doubtless no disease so hopeless in its progress and results that we shall not find it to be capable of alleviation or prevention, and the prospect is not bad for an improved knowledge where there are so many inquirers. It is from stagnation of opinion, hopelessness of more knowledge, that the thoughtful mind recoils as from the death of all improvement in our art.

These form some of the considerations which have weighed with me in selecting "Phthisis, its Modern Theories and its Modern Treatment," as the subject of these short lectures. The young among us will not hesitate to reconsider the researches and opinions of former great men, while the older may excuse a reconsideration of questions with which they are already familiar, from the vast importance of the results, if results we are to have from newer teaching. It is also evident, as is indeed the case with all medical subjects, that this disease does not stand alone, that it is impossible to isolate it from considerations of general pathology, and that the laws which regulate its progress and results are conditions common to many diseases. There is here no special pathology, as there should be no special treatment; and we may well quote the well-known saying of one of the most thoughtful of our predecessors, that "it demands a higher discipline than any mere knowledge of auscultation rightly to comprehend it." I propose to consider briefly, then,

the older doctrines of phthisis, and to compare them with the later; to point out the morbid changes, their causes, and their relation to the progress of the affection; to inquire into the causes of the secondary disorders, and to consider what has been advanced as to the germ origin of phthisis, and the evidence in existence as to its contagiousness. I shall also ask, as arising from these considerations, how its treatment is to be guided; on what principles we should advise the various climates; and whether the local disease in the lung be the main condition to combat, or if we are to rest contented with remedies of a nutrient and general character. If in this review I should appear to generalize rather than to descend into too much detail, you will, Sir, I hope, attribute it to the largeness of the subject, and to a desire to bring before you such salient points as come in prominent relief before each of us in daily practice. I am also addressing, and with much secret diffidence, an audience most highly informed on this very subject, many of whom are the advanced pioneers of our knowledge.

Reviewing the literature of phthisis from the earliest times of which we have any record, we may say that the Greek word for *waste* expresses the idea of the disease when it was uppermost. The wasting of the bodily tissues was the earliest, the latest, and the most marked symptom of the disease throughout. It became evident before cough and expectoration, it fluctuated with the patient's other conditions, and it ended by exhausting him to the grave. We know now from auscultatory signs that this waste is greatest when the morbid product in the lung is breaking up, but before stethoscopes were invented the fact could only be proved by the increased amount of expectoration which then occurred. Fever, indicated by chills, heats, and sweatings, also coincided with increased waste of tissues. The correlation of these symptoms with waste was not understood. We now know that the waste itself and the débris of tissue poured into the blood are direct causes of the high temperature, and that there is a strict coincidence between three conditions—(1) active lung irritation, (2) tissue waste, and (3) high temperature. But we may take it that the ancient view before stethoscopes was that waste was the leading and most incorrigible symptom.

It remained for Laennec, Bayle, and their followers to describe and map out by physical signs the nature and amount of lung disease. We are familiar with their teaching. The grey milky tubercle deposited sparsely or thickly in portions of the lung underwent degenerative changes. The masses caseated, ran together, softened, and in their softening broke down the surrounding tissues of the lung, strangled its nutrient bronchial as well as the pulmonary proper vessels, cut off the circulation, and caused the death of the part. A cavity more or less irregular in size and shape, resulted. Inflammatory products surrounded, and were a consequence of, this softening and disintegration. The secondary congestion so commonly observed in advancing cases of disease at the base of the same or opposite lung were fresh deposits of tubercle, only to be accounted for by the lowered constitutional state of the patient—the tubercular cachexia, as it was called. He got an unhealthy inflammation, involving all the tissues of the lung, though why he should have had any affection of the opposite lung does not appear from Laennec's reasoning. In like manner the well-known changes in the intestines causing tubercular inflammation of the mucous glands took place, and diarrhoea precipitated the fatal issue. The constitution or diathesis in which this

occurred was called scrofulous, and glandular swellings tending to slow inflammatory change and caseation took place in the cervical, mesenteric, and other lymphatics. These, like the tubercle in the lung, were the secondary results, so to speak, of a primary cachexia or constitution and of the tubercular habit. I take it that this is a fair description of the theories of Bayle and Laennec. After an investigation of many thousands of cases of phthisis I do not think it can be taken to account for all the phenomena of that disease, but this I shall again notice. What the discoverers of auscultation did prove was this. They recognized certain morbid changes in the lung which they called tubercle. They noticed its physical alterations and its tendency to degenerate, and they gave us a means of defining and even measuring the progressive destruction of lung tissue, which resulted as these masses softened and involved the surrounding parts. I do not know that auscultation has added much to what Laennec taught us about phthisis. He was wonderfully accurate and perfected physical examination in a marvellously short time. What more do we know now of the signs of cavity or of pneumothorax than the knowledge he left us? We have refined on his teaching no doubt, especially in the diagnosis of incipient disease, and some phenomena of effusion into the pleura and pericardium, but he gave us a masterly method of identifying changes of lung structure. Nor was his pathology at fault. He did not go far enough. So far as his description of tubercle goes it is verified by daily practice, but it was all tubercle with him. He did not allow cases of phthisis which were originated in inflammatory change, and in which there was no tubercle at all. It would be unjust to the memory of Addison not to point out that he in England was the first to hold that inflammation is an occasional and common cause of phthisis. His beautiful illustrations are accurate pictures of the results of inflammatory change. There is, then, a phthisis without tubercle, and in many post-mortem examinations no tubercle is to be found. Again, the secondary deposits of tubercle, which often surround old inflammatory products breaking up in the lung, do not appear to have a fair place in Laennec's descriptions. The secondary congestions in the base of the same or the opposite lung were regarded as fresh tuberculous attacks, and the mechanical theory of morbid matters carried and deposited on the pulmonary tissue is modern, and found no place in his work. The influence of hæmoptysis, as now recognized by many, cannot be said to have been noticed fairly by the French school. The mechanical effects of effused blood insufflated into the pulmonary tissue, and forming clots which lose color and become encysted or undergo the changes of caseation, were no doubt often mistaken for tubercle.

Again, in criticising the French school of that period by the light of experience at the bedside, I fail to discover in their teaching the division of cases according to their progress and duration and according to the structure of lung invaded, and the changes of a fibroid nature undergone. This, I hold, to be entirely due to the modern English school. In Laennec's time a cavity in the lung meant the third stage, the final consummation of the disease, the almost immediate death of the patient, and the abandonment of all hope. We now sit down to treat cases of cavity, to promote their shrinking, to diminish their secretion, to attack them surgically and drain them, and some of the most prolonged instances of invalid life with which I am acquainted are in persons with a single cavity in the lung. I had one such case

under my notice for thirty years, many for periods of ten and fifteen years; and I have no doubt that the experience of all of us will bear out this statement.

Again, the whole series of chronic changes in lung tissue which have been called fibroid, and in which the lung is condensed and contracted and fresh fibroid tissues developed throughout its structure, extending in bands from the thickened pleura, closing up old cavities, strangling its bloodvessels, and leaving, in fact, only bronchial tubes which undergo dilatation, this condition, which supervenes more or less in every case of chronic phthisis, and which often prolongs life indefinitely after the patient has undergone thickening of the lung, softening of tuberculous or inflammatory deposit and cavity, had not been described till modern English observers depicted it.

In contrasting more recent views and observations with those of the Laennec period, there is one of surpassing importance which seems to pervade the theories of all lung affections, and its consideration leads us to review the modern German pathology. There was so much of form, consistency, and precision in the French doctrines. It was so convenient to have found one single element, tubercle, with definite form, and history which underwent changes uniform and calculable, to each of which a stage of disease might be assigned, and from which the duration and result might be calculated, that it is easy to see now why it was accepted both by pathologist and practitioner. To the former it was a concrete idea, a unique morbid product, recognizable by its history and its appearance; it had a definite life or underwent changes, sooner or later, which converted it either into cheesy or chalky matters, and if a new crop appeared a like process could be predicted; while to the practitioner it was also a definite quantity; he could explain it to his patients' friends, and appear to be precise where, perhaps, he was not quite true! But to the whole profession, and to the public, its very precision and the known and invariable course which tubercle follows when once established in the lung, stamped it as incurable and hopeless. Now, this state of things was the death of all progress in medical knowledge and the stagnation of all hope of a remedy. The very precision with which the malady was known rendered investigation useless and advances impossible. It will be in our memory, however, that out of this hopeless mass of cases, all of one gloomy aspect, there stood out certain ones which refused to follow the given course to death, in whom, if there were tubercle, it neither killed nor prostrated them. Persons were known to live for years with cavity in one lung, and eventually, perhaps, to die of something else. Was it, then, possible that if this tubercle always runs a certain course there may not be other morbid products in the lung giving rise to the symptoms and signs of phthisis, which run a different course, some of which may tend even to recovery, and others simply to alter lung structure, but not to destroy it? I doubt not but that some such reasoning as this struck anxious observers who were sick of regarding the sphinx of phthisis, and, unable to answer its questions or account for all its phases on the old French theory, were not content to be absorbed by the problem, but rather received a new impulse towards its solution. The modern German mind, pretty commonly in opposition to the French, rushed at once to the conclusion that if there be such a thing as tubercle its presence was only an occasional result, and not a primary cause of phthisis. Tuberculosis is a danger incurred by the phthisical, but the diseased is seldom initiated by it. All Laennec's teaching

was wrong. Tubercle was not a new growth of specific nature which formed the essence, so to speak, of phthisis. The cheesy transformation so commonly found in consumptive lungs did not result from tubercle; they might be due to many causes, but chiefly to inflammatory products. That bronchial, peribronchial and pneumonic deposits often pass for tubercle; that the miliary form is the only tubercle; that those masses of infiltrated lung which Laennec called "stuffed" with tubercle are really masses of inflammatory products, the result of catarrhal pneumonia; that in many cases there is not a single tubercle in phthisical lungs. Then as to the origin of the disease, Laennec had been precise in assigning it to a constitutional cause; it never arose out of acute or chronic pneumonia; hæmoptysis is never a cause, though a frequent result, of phthisis. It never arose out of a catarrh or neglected cold, a bronchitis developing phthisis being not a primary genuine cold, but catarrh caused by irritation of the lung from already existing tubercle. His mistake was not that tubercle is a new growth, but that condensations of lung which have quite a different origin are also products of a development of tubercle. In enunciating these startling propositions the well-known German, Niemeyer, naïvely remarks that "pathological anatomy is in advance of clinical medicine." Well for its truth if it be not sometimes in opposition to it! In estimating the influence of the various theories of phthisis on its treatment, I shall have occasion to call your attention further on to this opposition in views, and to ask you whether, in your observation, phthisis arises from neglected colds, or whether the catarrhal symptoms have become developed in the course of the phthisis?

The well-known teaching of the modern school is that the primary block of the lung is due to pneumonia or inflammatory products, and I beg your patient hearing if I briefly describe it.

Catarrhal pneumonia begins in catarrh of the smallest bronchi, extending to the alveoli, which become packed with exudation rich in young round cells. The acute cases are a frequent result of measles and whooping-cough. Under favorable circumstances the cells fill with fat-globules and disintegrate, and the contents of the alveoli become fluid and are absorbed or expectorated. In less favorable cases, the lung tissue becomes consolidated, the cellular element increases in the alveoli, fatty changes are incomplete, the cells lose their rounded form, and shrink into irregular shapes; this represents cheesy transformation. Every form of pneumonia may end in this necrosis of the cells and caseation. In this process the walls of the alveoli are pressed on, their bloodvessels become compressed and the walls are broken down, and the form of destruction of lung tissue with which we are familiar takes place. In chronic catarrhal pneumonia a formation of connective tissue fills up the collapsed cells, so that the lung becomes tough and impermeable to air. The pleura is thickened and adherent, and from it bands extend throughout the lung, contracting its volume as the tissue shrinks; the whole side is drawn together, and the bronchial tubes become dilated, giving rise to the phenomena of cavity. These are the more chronic and favorable cases. The diaphragm is drawn up and the heart displaced in their advanced stage.

But the two points on which the German and French schools are at issue are the influence of cheesy transformation of the morbid products in the lung and the secondary eruption of tubercles in chronic cases of phthisis. It seems acknowledged on all sides that cheesy deposits, in breaking up, give rise to or are followed by an eruption of miliary

tubercle, either in the neighboring part of the lung or in the opposite lung. Daennec described this, and it was known that it is at the period of softening of such masses that the appearance of fresh tubercles occurs. Thus cheesy transformations in some part or other originate tuberculous, which is in this instance a secondary disease. Cheesy masses in some way infect the system. Buhl says that miliary tubercles constantly depend on pre-existing cheesy products. Tuberculosis is an infectious disease caused by reception into the blood of the tubercular poison. He compares it to pyæmic septicæmia. Laennec knew that a secondary eruption of tubercle takes place in a lung already broken down by primary disease: he called it "secondary;" Niemeyer called it a "complication;" but both referred it to a previous caseation of the mass in the lung, which the German said was inflammation, but the Frenchman "tubercle." In either case we see it was regarded as an infecting agent, and this is important as leading on to more modern views still. I must beg your patient indulgence in this recapitulation. We are taking note of the successive theories of phthisis; we are watching the evolutions of thought in observers at different dates; and we must remember that all this time phenomena other than those of tubercle were being equally studied, and old doctrines of disease overturned.

In examining the relations of scrofula to phthisis, we shall find that cheesy transformation of the products of slow inflammations of lymphatic glands is held to be an infecting agent, and that such matters carried in the blood, or by the lymphatics, are deposited in distant parts, and there, as in the lung, originate phthisis, or in another lymphatic far from that originally affected. Thus, we have a step in the direction of blood-poisoning—septicæmia—or at least that morbid products are so carried and deposited, for septic they are not. If this be the origin of phthisis, the inflammation theory is interfered with; but, again, what is it which has originated the scrofula which started the lymphatic enlargement? Are we then driven back to the old "diathesis," or "constitution," which covered so much ignorance on our parts? In pursuing this line of thought, we are compelled to ask why some persons get catarrhal pneumonia—that is, a block of a portion of lung by inflammatory products which will not liquefy nor be absorbed, but undergo cheesy degeneration—and others get croupous or sthenic pneumonia, by which a fibrinous exudation is poured out into the alveoli of the lung, nay, of a whole lung, and in the course of fifteen or twenty days is wholly liquefied or cleared out, leaving the delicate structure of the alveoli unimpaired? These two diseases are so unlike in their morbid products, in their symptoms, and in their results and sequences, that they have no right to the same name. Indeed it was in an evil hour that such identity was stamped on them, for they do not possess any point in common, excepting that of their seat. They both affect the lung, but this may be said of several other disorders.

The German school will not acknowledge "constitutions," or delicacy of system, leading to those deposits which will not clear up, but go on to poison the system, and produce like localization in other organs. They say such persons have a "vulnerability;" that tuberculosis is "not heritable," but that "the disposition to it is." But we know that lung attacks leading to cheesy infiltrations occur chiefly in delicate and badly nourished persons, whose inflammations tend to an abundant production of cells, and thereby to cheesy metamorphosis, and that cheesy metamorphosis anywhere may lead to tubercle. So much for the

nature of the product which blocks the lung, and which is known to end in phthisis. We ought to distinguish four kinds: (1) The inflammatory exudation, which is not tubercle; (2) the miliary tubercle, which is secondary and rare, as the Germans say, but primary and common according to Laennec; (3) the cheesy transformation, which is common to all; and (4) the developed connective tissue, which contracts and hardens the lung into a fibroid state.

There is another consideration to which I must draw your attention, and that is the localization of the morbid product in the lung; and it does not appear that this has received sufficient attention. I do not allude to the lobar or lobular arrangement of deposits, nor to the interesting question why the apex of the lung suffers most in phthisis, but rather to that portion of the lung structure which is the seat of the morbid product, be it inflammatory or purely tubercular. I take it that here will be found points of difference in the purely inflammatory as compared with the other forms of structural injury to the lung. Perhaps we may make this more clear by asking why it is that lung mischief is so productive of ultimate injury to the individual, giving rise to fever and wasting and all the pernicious results of phthisis? If it were due merely to the amount of pulmonary space lost, the ordinary croupous pneumonia which blocks with the greatest rapidity a large portion of the lung would give rise to these symptoms. But the phenomena of acute pneumonia are altogether different from those of phthisis. We have a sudden attack, very high temperature, and an exudation of a fibrinous character into the alveoli of the lung, in many cases blocking the entire organ—even the opposite lung may be attacked in sequence, and the respiratory space be lost over almost the whole of both sides—and yet the patient recovers. In practice we say that if the heart be strong enough to drive the blood through the obstructed lung, and does not fail in the effort, the patient may get well. Especially is this the case in that turn or crisis of the disease when the exudation begins to break up and liquefy. The case might almost in practice be called a heart, and not a lung, problem; and those who support the circulating force at the heart will have the greatest number of cures. The lung is not diseased in its structure during such an attack, its terminal cells are filled up, but that is all, and we know that perfect recovery may and does daily take place, the delicate elastic structure of the alveoli being found entirely unimpaired after the exudation has been removed.

Now compare this with the smallest exudation or product of inflammation which has broken down the alveolar walls and infiltrated the peribronchial and interlobular tissues, and we shall see at a glance wherein the difference lies. So long as the alveolar walls are not broken down there commonly is recovery, but infiltrations into the proper lung tissue are not so recovered from. The results in the latter case are not liquefaction and absorption of the exudation, but first mechanical pressure on and strangulation of the nutrient vessels of the lobule, causing the death of the part, so that the infiltrated material is compressed, the alveolus collapses, and those changes are initiated which end in cheesy transformation. How is it that a pneumonia which is not resolved after about two months becomes a phthisis? We believe that it is because in the very earliest phase, that of exudation, the interalveolar tissue has been invaded by the inflammatory product, and that we are not dealing with a portion of lung which has its alveoli filled up with fibrin, but a portion where the alveolar walls have given way and a diffused de-

posit has solidified the whole lobule and its surroundings. This is not a croupous pneumonia at all, it is an insidious deposit in the lung tissue, and will have a different ending from that of sthenic pneumonia.

As I have commented on the errors of the French school as seen from one point of view, so it must be remarked that the German has fallen into errors easily pointed out. Having the great task of enunciating new and true doctrines regarding the inflammatory nature of many products in the lung hitherto called tubercle, it was not unnatural that they should have been led into the common exaggeration of making all phenomena of phthisis harmonize with the new theory. Thus the common origin in catarrh was implied when the name was adopted; the term was no doubt given just as pneumonia was forced into the service in order to inform the medical mind once for all that the exudation in the lung was of inflammatory origin, and must have originated in the ordinary causes of irritation of the air passages of which cold and exposure are the chief agents. But we have seen how unlike a true pneumonia is to the so-called catarrhal variety in its seat, the nature of its products, and in its termination; and so we may say of the term catarrhal, which has misled many a practitioner, and induced a prognosis not verified by the result. Its influence on treatment must also be remembered, and the question will arise whether what is suited to a catarrh is applicable to a phthisis. In adopting this word we appear to have gone back to the old vulgar idea that all consumption came from a neglected cold, and that hot and close rooms and means to relieve bronchial irritation are the best remedies to adopt.

There is another statement of this school to which I must advert, and it will be remembered that my object is not to subvert any doctrines, but, as will be seen later on, to show by a study of the changes of opinion on phthisis how a gradual evolution of the most modern teaching has taken place, and to follow the line of thought in the minds of successive masters. Is hæmoptysis ever a cause of phthisis? Is it ever actually the first in the train of symptoms, the one which initiated the disease? Laennec and Louis lay it down that hæmoptysis indicates that tubercular mischief is already established in the lung. The irritation of the tubercle causes congestion, and hence the hæmorrhage. Niemeyer says that capillary hæmorrhage, bronchial or pulmonary, often induces phthisis even where there was no tubercle, and that in the majority of cases irritation of the lung follows hæmoptysis. The blood which remains and coagulates in the bronchi and alveoli becomes a cause of phthisis. In some rare cases he says hæmoptysis is not a cause, but a consequence, of pneumonic processes which lead to consumption; but the rule is otherwise, and hæmoptysis is most ordinarily a cause of the disease which is to break up the lung. Thus, as regards the earliest stages of phthisis, we have two sets of conflicting opinions. As regards clinical observation, we see a large number of cases initiated by an hæmoptysis. Every practitioner will endorse this observation. The theory of course is that the blood retained in the alveoli, together with pneumonic infiltration, undergoes cheesy change, and this is followed by breaking down of the lung, or by an eruption of miliary tubercle. We cannot forbear from asking the question why the hæmoptysis should occur at all if there be no preceding disorder of the lung. Is it within our clinical experience as a fact? Why should a portion of lung suddenly permit of hæmorrhage? We know that the pulmonary structures are capable of undergoing immense strain from sudden and prolonged exertion, and, further,

that when a hæmorrhage occurs from such causes, or from cardiac valvular disorder, that lung disease, and especially phthisis, does not follow. It is true that hæmoptysis is in a vast number of cases the earliest symptom of phthisis to which the attention of the medical attendant is called, but do we not almost always find that for weeks or months previously the patient has been slightly losing flesh, has felt unusual weakness, has had some suspicious febrile symptoms, or has had slight dry cough? Taking the German theory of a pneumonia as the ordinary cause of phthisis, we can see how the influence of hæmoptysis as a primary cause came to be insisted on. If there was anything morbid in the lung before the hæmoptysis, it was most likely to be what Louis and Laennec said it was—tubercle! And it was necessary to combat this, and to account for the hæmoptysis as the first evidence of the congestion and the inflammatory exudation which were to follow. Here, again, pathology was in advance of clinical observation, for the facts of practice do not bear out the theory. People do not get a consumption because they spit blood, but they spit blood because they are consumptive; and insurance offices and those who advise them are right in attributing that meaning to the symptom. But, in truth, the Germans want to prove too much—their statement that inflammatory products often passed for tubercle is abundantly proved without this attempt to account for a symptom which seems to tell against them. Hæmoptysis is commonly due to something already wrong in the lung, be it tubercle or not, and all experience proves it. In those cases where it is not, it is harmless, and probably due to cardiac causes, or general fragility of the whole vascular system. I have myself records of about three hundred cases of hæmoptysis which did not originate nor result in any disease of the lung.

I venture to recall your attention to that remarkable and able debate on the connection of tubercle with phthisis in 1873, at which, Sir, you yourself presided. At that time we had not fairly reached the doctrines of infection, nor had bacilli been discovered in the sputa of phthisis. The medical mind of this country, which had long reposed on the doctrines of Laennec and Bayle, had been roused by the strong assertions of the German school which I have described, and the result was a declaration of faith on the part of some of our ablest inquirers. The solid observing English mind, which is conservative of old opinions while impartially open to every novelty; which is little given to belief in the dogmas of any school as such, but waits for their verification by evidence, was ably represented by the leading speakers on that occasion. As in surgery it used to be said that operations were invented in France but made safe in England, so the lighter and more ephemeral part of German theories are often reduced here to the level of facts which have been proved by investigation, and if found to bear such crucial test are assimilated with medical science, but, if weighed and found wanting, are rejected. I take it that in no country are the names and doctrines of great names so worshipped as in Germany; but I must maintain that no country is so practical as England.

I will venture briefly to recapitulate a summary of the views of the prominent speakers on that occasion, in so far as they were not contradicted. It was recognized that under whatever name, tubercle or otherwise, it might pass, that a product of known anatomical appearances was found in the lung in phthisis; that caseation is not invariably tubercle, but often results from inflammatory products; that a new growth takes place in the walls of the alveoli in all cases of phthisis, leading to

destruction of their nutrient vessels; that this does not take place in ordinary acute pneumonia; that caseation was not due solely to inspissation of inflammatory products, but to a new growth in the walls of the alveoli, with which destructive changes in the lung are associated almost uniformly; that if this growth dies quickly, a rapid caseous change takes place, but if slowly, a fibroid change, leading to the well-known alterations in the lung structure that bear that name; that all these changes are manifestations of the disease, and that all occur in the most typical form of acute tuberculosis; that tubercle may occur without inflammation of surrounding tissues, or that it may be secondary to inflammation.

Dr. Wilson Fox states that implication of the alveolar wall is the most constant and typical appearance in the process of tuberculization. As regards the dispute about inflammation and tubercle, he considers that both may arise simultaneously and that inflammation may give rise to secondary growth in the alveolar walls, which is a main cause of phthisis, and that the causes of tubercle may be the causes of inflammation. As regards the nature of the so-called tubercle, he is borne out by Dr. Burdon Sanderson, in considering it to be a lymphatic overgrowth, produced by irritation under special circumstances, anatomical or constitutional, and he believes that adenoid or lymphatic tissue is found in the walls of the air-vesicles, and that as lymphatic irritation may prevail in any part of that system, so it may show itself here. The boundary line between tubercle and inflammation cannot be accurately defined, but there is no doubt that the tubercular growth precedes the caseation. We come now to another element in the case, and that is that certain constitutional conditions are essential to the production of tubercle. Any irritation of the tissue may, in the presence of local or constitutional predisposition, give rise to secondary growths, diffused or circumscribed, which constitute tubercle, and which may be the source of further infection, and that with or without antecedent caseation, although this stage, and that of softening, appear to be most favorable to the change. The real agent in infection is the small-celled growth in the walls of the alveoli.

Again, attention was called to the fact that irritants introduced under the skin of the rodentia give rise to lymphatic deposits in the lungs, liver, and spleen; even the irritation of a seton has done so. It was considered that over-crowded corpusculum in any organ may give rise to similar processes elsewhere, but Dr. Moxon thought that there was no phthisis without caseation, and that tubercle was another phase of inflammation, which latter can cause caseation, and so enter the system. I believe it may be stated with truth that no speaker upheld that common catarrh can originate caseation, and in this view it was pointed out that the initial stage of phthisis is local and not diffused as catarrh. Finally, it may be said Dr. Wilson Fox spoke the sentiments of the majority of those present when he said, "Tubercle tends to multiply, but can it be produced in the human subject by indifferent caseous products or by any inflammatory change not associated with a peculiar liability of constitution? I strongly doubt both."

It will be seen, Sir, that the tone of this debate was broad as regards the foreign schools, but accepted the data of neither. You will have noticed also that the whole debate turned both on the nature of the product in the lung and the changes which it undergoes, but also very much on the part of the lung which was so injured. If the doctrine is no caseation or no tubercle, then no

phthisis, it is also no less strongly that if there be no new cell-formation crushing and destroying the walls of the alveoli, then also there is no phthisis. The recoverable cases are those which after inflammatory or tubercular or catarrhal attacks remain with the alveolar walls intact. Destruction of alveoli is never recovered from, there are collapse and thickening of that part of the lung, but there is no restitution of structure and no vesicular breathing in that part again. Localization of disease rises into great importance. We used to think that the consumptive died of a constitutional irritative fever, but, tracing their symptoms alongside of the physical signs, we now know that their fever and their waste are coincident, and that it is just then that the tissues around the alveoli and in the peribronchial spaces are filled with a new cell-growth, which rapidly proceeds to caseation and softening. We also know that at this very time a mass of detritus of inflammatory or tubercular products is being carried into the blood and lymphatics, and deposited in other parts of the system, and that high fever wastes the patient while other organs or the opposite lung is being infected. Whatever initiates the disease this secondary result seems as manifest as the spreading of a fire in a dwelling, while, like the latter, the mystery remains of the originating causes of the combustion.

Clinical Lecture

ON

A RAPIDLY SUCCESSFUL TREATMENT OF ERYSIPELAS.

Delivered at Charing-Cross Hospital.

By RICHARD BARWELL, F.R.C.S.,

Senior Surgeon to the Hospital.

GENTLEMEN—We are at this institution fortunate in being almost entirely free from those diseases which have been called "hospital plagues"—pyæmia and erysipelas. Since this building has been reconstructed I have had to do with but one case of pyæmia originating in the wards. Some cases from without have been received, and those of you who have been with us long enough to remember those instances will also remember that the disease was not communicated to any other patient. Within the last two months I have had three cases of erysipelas here and two elsewhere, the treatment of which has been peculiar, while its very rapid success must cause much thought and consideration upon the relationship between its *modus operandi* and the morbid cause of erysipelas. I will shortly relate these cases, only premising that the plan I adopted in Case 1 is not that to which I desire to direct your attention—it merely led me to it.

CASE 1.—Miss —, aged thirteen was brought to me in October, 1882, with a diseased metacarpal bone. I found a large portion of the shaft necrosed and the hand a good deal swollen. On Oct. 19th, I removed the sequestrum (the greater portion of the shaft) through an incision a little under an inch and a half long. On the 23rd, a spot of erysipelas, with the usual dusky hue and hard boundary of cessation on the skin appeared—not at the wound, but a little above the ulnar styloid process; this was rapidly spreading. I painted the part and surrounding healthy skin with glycerine, and dusted over it boracic acid, making a tolerably thick crust, directing that more be applied wherever it flaked off. The inflamma-

tion disappeared in nine days—viz., she was well on Nov. 1st. But during the treatment I found that the paste did not keep on well, becoming detached in flakes, and that where this detachment took place the inflammation did not clear up as elsewhere, although there was on the skin a considerable dusting of the antiseptic boracic acid. This led me to think of some more sticky material, and my memory reverted to twenty years ago, when I think it was Mr. French, then of Marlborough-street, who told me he used white lead paint. I confess I attached at the time little importance to the matter, and it had apparently faded from my memory. However, since the above case seemed to show that it was not the "germicide" drug, but the exclusion of air, which produced the benefit, I determined to try a thick coating of paint on the next occasion. As chance would have it, this soon occurred.

CASE 2.—George F—, aged six, had fallen, five days before I saw him, on some sharp object, cutting his knickerbocker stockings and inflicting a pretty deep wound over the patellar tendon; this had been poulticed. On Nov. 22nd, at 6.30 P.M., I was sent for to see the child. I found the wound dry and harsh-looking. Over the tendon of the biceps and in the popliteal space was an erysipelatous blush, with hard sharp edge and rather considerable swelling. The child was fretful, irritable, and evidently in pain; tongue rather foul; temperature 103.2°; pulse 117. I sent for a pound of white lead paint, and painted the whole part inflamed and a little beyond, leaving out the wound, which was dressed by pressing into it a little cotton-wool soaked in a 5 per cent. solution of boroglyceride. Two grains of grey powder and five of rhubarb to be given at once.—23rd (9.30 A.M.): About three-quarters of hour after I left the child had become quiet, and asked for some bread and butter, which with a cup of milk was given; he then fell asleep and passed an excellent night. Bowels have not acted. Temperature 99.7°; pulse 90. Where in a few places the paint had cracked it was renewed. There is nothing more to remark in the case. The temperature became normal the next evening, and did not again rise. In seven days the epidermis was desquamating, bringing away the paint gradually and in patches.

CASE 3.—George F—, aged thirty-nine, was in the hospital with a fractured tibia. On the outer side of the leg was a wound, which did not communicate with the fracture. On Dec. 12th, having been in the hospital five weeks, he had some shivering, and his temperature rose to 101.8°. On the next morning erysipelas was found in the neighborhood of the wound; the part invaded was at that time about two inches and a half in diameter. On the 14th, when I saw the man I found him undergoing a severe attack of cutaneous erysipelas, which by this time occupied the whole leg, but did not extend above the knee. He said he was in considerable pain, and that his leg felt as if it was on a slow fire. Tongue slightly furred; temperature 102.1°; pulse 108. He had already been ordered a purge. I directed his limb to be coated with white lead paint. On the 15th he told me that in half an hour after this application the pain entirely ceased. Temperature normal; pulse 98. In this case my then house-surgeon misunderstood my wishes and removed the paint with turpentine. I saw him the same afternoon, and ordered its reapplication, as the skin, either from the action of the turpentine or by non-cessation of the disease, was a little red. He did unremittently well.

CASE 4.—Jane McK—, aged five, has pathologic dislocation of the hip, with necrosis about the

head and neck of the femur. The sequestra had been removed, and a drain through to the back of the thigh established.—Dec. 19th: She had shivering and vomiting, with a temperature of 103.6°.—21st: Erysipelas¹ of the thigh and buttock; the whole part painted. In the evening the temperature was 99.4°. She went on perfectly well. In eight days the paint was peeling off, and the skin quite normal.

CASE 5.—Robert L., aged thirty, received a scalp wound over the lambdoid suture of the right side on December 26th. He was treated as an outpatient. On Jan. 15th he came back with severe erysipelas of head and face, which appears to have been going on some days. A purge was ordered.—16th: I found him with his head and face wrapped in absorbent cotton-wool. This was removed. His hair had been already cut from both head and face. Both were much swollen, the eyelids were so large that they could hardly be parted sufficiently to see the eye, the lips and the *alæ nasi* also were generally swollen. Temperature 103.8°, pulse 114. Complaints of much pain. Ordered to be painted; no other remedy to be used.—17th: Mr. Wyborn (house-surgeon) found before painting some boggy patches on the scalp; these he punctured evacuating pus. I directed that the head as well as the face be now painted. The man, however, is much better, the temperature lower. He is free from pain.—18th: The patient appears convalescent, his temperature is normal, his pulse steady (98), and he is desirous of more food. The man assured me that within half an hour of the application the previous severe pain entirely disappeared.—22nd: Patient very anxious to go out but I keep him a day or two that the paint may come from the hair.

The temperature chart ran thus:—

	Morning.	Evening.
January 16th . . .	103.8°	102.1°*
" 17th . . .	99.8	100.2
" 18th . . .	99.9	98.0
" 19th . . .	97.7	97.9
" 20th . . .	96.6	97.1

* Between these times paint applied.

And so on, the thermometer never rising again beyond 97.3°. I do not know why the temperature was so low, unless it was a personal peculiarity; the man was certainly not feeble.

These cases² are, I think, sufficient to show that a very great effect is produced upon erysipelas and its congeners by covering the surface with white lead paint. This is, I believe, entirely due to exclusion of air; the lead of that compound is in an insoluble condition; nor do I believe that the inflamed skin is in a state to absorb any material applied on its surface; by the time that it has recovered the lead is separated from the living tissue by a tolerably thick layer of desquamated and dead epidermis.³ Moreover, lead as a solution of the acetate has been applied from a very early period, and as far as I know without any appreciable benefit to erysipelas.

Now, gentlemen, I began this lecture by speak-

ing of erysipelas as one of the so-called hospital plagues; it has long been known both in an endemic and epidemic form. Since the germ theory of disease has been propounded this has been considered, by those who accept in full that hypothesis, to be a typical germ-produced disease. It certainly comports itself after that fashion. Nor need I insist upon all the evidence to be found in every medical and surgical work that erysipelas is a blood disease, not merely a local cutaneous inflammation, but an infection by putrescent or other morbid poison of the whole system; that in this particular medical and surgical erysipelas do not differ, although it is certain that the idiopathic form of the malady very often begins in the fauces, while the traumatic variety has a tendency to commence in or near the wound; but that this marks not any difference in the sort or action of poison, but only a diversity in its place of entrance. And yet here, in a number of well marked cases, you see this disease yield to a mere local application—to simple occlusion of air; yielding, that is to say, not hesitatingly or doubtfully, but at once and unmistakably. I will not now take up your time (for clinical teaching should concern itself not with speculations, but with facts) by attempting to show you how this may perhaps happen, but must nevertheless tell you that I am by no means prepared to discard the blood-poison etiology of erysipelas; yet why a general systemic disease should be thus cured by local treatment is very curious, and of course many more trials and successes must be realized before so strange a doctrine can be accepted. Fortunately our opportunities of seeing erysipelas are very few; it may be months before any, even slight, cases occur. I hope other surgeons may soon report to us their experience in this matter.⁴

P.S.—Since the above lecture has been in the printer's hands, I have had, through the kindness of Dr. Bruce, the opportunity of treating a case of idiopathic erysipelas, with equally rapid success. A lad, aged nineteen, presented himself on Feb. 16th, with erysipelas of the face, in its early stage. The fauces were much inflamed, red, and swollen; the inflammation passing forwards along the nares, and up the lacrymal duct, had spread to the *alæ nasi*, as also to the lower eyelid, which were red, hard, swollen, and still were enlarging. Temperature 102.4°; pulse 120. He was sent to bed, a purge was administered, and his face was painted with white lead paint. This application was renewed twice; no other remedy was used. In six days the lad was well. Mr. Wyborn was good enough to examine the urine. It was quite normal. Tested with hydrochloric and with hydrosulphuric acid it gave no precipitate, showing the absence of lead.

—It is stated in the *South London Press* that in the Newington Infirmary there are thirty-two beds on the basement, and the patients in some cases are obliged to step from their beds on to the bare asphalt; that there is no nurse for the place, and the patients have to do the best they can for themselves, without assistance from others; and that there are altogether in the infirmary eighty cases above the certified number.

¹ The inflammation, though it included the skin, was evidently also deep; the disease might be called either cellulitis or phlegmonous erysipelas.

² A girl at the Cripple's Home, affected with erythema nodosum in unusually large blotches, was treated in the same way with like benefit and similar mitigation of pain.

³ Dr. Mitchell Bruce, to whom I showed the last of the above cases, has been good enough to call my attention to the following passage in Wood's Therapeutics, p. 39: "Plumbi carbonas as white paint is a most efficacious dressing for fresh burns. Care must be taken when a large surface is involved, as lead colic has been caused by its absorption."

⁴ White lead paint, obtainable at any oil and color shop, is made by rubbing up the carbonate of lead with linseed oil, and for the purpose in question, as indeed also for ordinary use, is mixed with turpentine as a "drier." When applied over hairy parts the surface should be shaved, or at least the hair cut very close. When growth takes place the dried paint is pushed off in little patches, and if patience be taken for two or three days, until the hairs are long enough (about one-tenth of an inch) to admit between the skin and the little flake of paint the blade of a pair of scissors, removal is easy and painless.

Lumleian Lectures

ON

URIC ACID: ITS PHYSIOLOGY AND ITS RELATION TO RENAL CALCULI AND GRAVEL.¹

Delivered before the Royal College of Physicians,

By A. B. GARROD, M.D., F.R.S., F.R.C.P., etc.,
Consulting Physician to King's College Hospital.

LECTURE I.

MR. PRESIDENT AND GENTLEMEN—On being requested to deliver the Lumleian Lectures for the present year at our College, I naturally felt much gratified by the honor, but, none the less, I should have hesitated to accept the responsibility of addressing you in my present capacity, had it not so happened that I was at the time engaged in completing some investigations which I had begun many years before. As these had relation to the production of uric acid in the animal economy, and to its morbid manifestations—subjects of deep interest to the physician—I thought that the results of these researches might not be altogether without attractiveness to my professional brethren, if they were made the subject matter of the present course of lectures.

Having, therefore, a subject to bring before you which contains some little novelty, and, as it were, breaks new ground, I put this fact forward as my excuse for appearing to-day in the capacity of your Lumleian Lecturer.

Let us imagine a partition separating the blood from the urinary excretion, such as, in nature, is found in the walls of the renal vessels; then uric acid, free or in combination, may exist either on the one or on the other side of this membranous partition; if on the one side—that is, in the blood—it originates symptoms which are referable to various organs; it may be deposited in the articular tissues, and produce the typical form of joint-gout, with chalk-stones; or it may affect the skin in the shape of eczema, or cause cramps, neuralgic pains, dyspepsia, etc., according to the part particularly selected. On these I shall not touch in this course of lectures, having had full opportunities of setting out my views and researches elsewhere. But uric acid is also to be found on the other side of our imaginary partition, that is, in the urinary excretion, and under certain circumstances, it forms morbid deposits, such as go by the names of gravel and calculi, and it is to these that I shall confine my attention, with special reference to their pathology and treatment.

In some animals, as the mammalia, including man, urea [$\text{CO}(\text{NH}_2)_2$, or $\text{CH}_4\text{N}_2\text{O}$] is the chief nitrogenized principle, and it is the one which is richest in nitrogen, containing as much as 44.66 per cent. It appears that the average quantity of urea excreted in the twenty-four hours is 512.4 grains, and that, for each avoirdupois pound, 3.33 grains are eliminated daily. It is in the form of urea, therefore, that the chief part of the nitrogen in a very large and important class of the animal kingdom is eliminated.

The next principle to be mentioned is uric acid ($\text{C}_5\text{H}_4\text{N}_4\text{O}_6$), which was formerly called lithic acid, and has recently been synthesized. This acid, combined with more or less ammonia, forms the chief part of the nitrogenized excretion of birds and

reptiles, as also of almost all invertebrate animals, and a small part of that of man and the other mammalia. It contains 33.33 per cent. of nitrogen, but, if estimated as urate of ammonia, as much as 37.83 per cent. Its properties, especially as regards solubility in water or the animal fluids, differ greatly from those of urea, for it is with the greatest difficulty that it is dissolved, requiring, when pure, as much as 8,000 times its weight of distilled water at about the temperature of the blood (100°Fahr.). The salts of this acid are more soluble, but yet, in comparison with others, only slightly so, and they and the acid itself readily crystallize out from the fluids in which they are dissolved. It is owing to this property of insolubility that uric acid, although it forms so small a proportion of the urinary excretion in man, so frequently is a cause of disease. In the first place, it may concretely in the kidneys, forming gravel and renal calculi, which, when they reach the bladder, if they remain there for any time, encourage the precipitation of a further quantity of uric acid or urates upon them, and thus vesical calculi are formed; or, secondly, uric acid may be present in the blood and lead to special symptoms in different organs, or become deposited in the form of urate of sodium in various tissues, producing much discomfort.

There is a third body—viz., hippuric acid ($\text{C}_9\text{H}_8\text{NO}_3$), which is found in the urinary excretion; largely in that of the herbivorous mammals; in small and varying quantities in the urine of man; but almost, if not entirely, absent from that of the carnivorous mammals. It will be seen from its formula that the percentage of nitrogen contained in it amounts to 7.82. Although hippuric acid has hitherto been regarded as a comparatively insignificant ingredient, at least in the urine of man, we shall, as we advance in our subject, find that it plays an important rôle in the metabolism going on in the system, one which, to us, as students of disease, is of deep interest.

It is in the form of one or other of these three substances, with comparatively slight exceptions, that the whole of the nitrogenized waste of the body is eliminated from the system by the renal organs, little or none escaping by any other channel.

As uric acid is the principle which will chiefly engage our attention in these lectures, and as a correct knowledge of the mode and place of its formation in the economy is of the utmost importance if we ever hope to arrive at the solution of the problem of the cause of calculi, and to develop some method of preventing their occurrence, and, more especially, as the views I have arrived at during the study of the subject differ so much from those held by almost all physiologists, I shall not attempt to apologize for occupying your time with the investigation of the nature of this substance.

Origin of Uric Acid in the Animal Economy.—There are, at least, two possible theories as to the formation of uric acid. Of these the first is, that it is formed during the metabolism constantly going on either in the system at large, or in special organs—such as the spleen, lymphatic glands, liver, lung, etc.; and that when formed, it reaches the blood, and is afterwards rapidly eliminated by the kidneys. From the point of view of this theory, the renal organs are merely the drawers-off or filters from the blood of the uric acid which it brings to them. For the sake of brevity, I shall, in these lectures, call this the *first* view.

Another, which I shall call the *second* view may be held. In this it is assumed that the kidney is the organ whose function it is to produce uric acid; that this principle is formed in the renal cells from nitrogenized matters brought to them

¹To economize space a few less important passages have been omitted from this report.—Ed. L.

by the blood; and that, in so far at least as uric acid is concerned, the kidneys do not act in any degree as filterers or strainers. There are few physiologists or pathologists, at the present time, who hold this opinion; and the discovery of uric acid in the blood, which I made in 1847, seemed, at first sight, to militate against it: for it appears to follow from the fact of the presence of uric acid in the blood, that it must be formed before the blood reaches the kidneys, and not in those organs.

In the course of our investigation into the value of these two views respectively, we shall have occasion to bring forward almost all the facts at present known with reference to the physiology of uric acid, and these require a satisfactory explanation before we can definitely arrive at any choice between the rival theories.

The two theories above mentioned may be shortly summarized as follows. In the first, the kidney is regarded simply in the light of a strainer or filterer of the uric acid which is found in the blood, and passes through to it. In the second, the kidney is held to be the actual producer of uric acid, and the presence of this principle in the blood and tissues is explained by resorption from the renal cells, a process which is scarcely appreciable in health, but becomes more and more marked in proportion to the difficulty which the uric acid has in finding its way to the uriniferous tubes.

In considering the physiology of uric acid, I must, in the first place, draw your attention to the fact that there are great differences between the urine of different classes of animals, both in physical condition and in chemical composition. In some animals the urinary excretion is very thin and watery; in others, it has the consistence and appearance of thick cream, these differences depending, of course, on the ratio between the water and the solid constituents of the excretion. The constitution of the solid portion of the excretion also varies much; in some urines the urea is abundant, the uric acid very scanty, or even altogether absent; in others, these two constituents are both present in large quantities; while, in a third class, the urea is either very small in amount, or entirely absent; uric acid, in some form of combination, constituting almost the whole of the solid portion of the urinary excretion.

1. *Mammalia*.—The urine of man we will not discuss at present, as we shall have to speak about it when dealing with the formation of renal calculi and gravel; it may, however, be mentioned in passing that, in constitution it closely resembles a combination of that of the carnivorous and herbivorous mammals, as, indeed might have been anticipated from our knowledge of the anatomical structure and the nature of the food of man.

The urinary excretion of the carnivorous mammals is a watery and heavy fluid, its specific gravity being sometimes as high 1070. I have found that of the lion and tiger to be 1063 and 1064, of a distinctly acid reaction, and a not disagreeable odor; nor is it liable, as has often been asserted, to rapid decomposition. The urine is rich in urea, so much so that often a single drop placed on a piece of glass will, after a few minutes, become a mass of crystals; and with nitric acid, it immediately becomes solid, from the formation of nitrate of urea. Uric acid is usually found in it, but in very small quantities, never, at least when the animals are kept in confinement and sparingly fed, reaching the amount contained in human urine.

No hippuric acid is found, at least under ordinary circumstances, in the urine of the carnivorous

mammals; a fact on which I wish particularly to insist.

Next, as to the herbivorous mammals. The chief points of relation and difference between the urine of these and the carnivorous mammals may be thus summed up. It is usually a heavy fluid. I have found in the horse the weight ranging from 1025 to 1045. In the elephant (female) it was 1033, and in the camel 1047; but only one examination was made in each case. In the cow and ox I have found it as low as 1014 and as high as 1035. It is always alkaline in reaction, except in the sucking animal, and of a peculiar but not unpleasant odor.

The urine of herbivorous mammal is rich in urea, less so than that of the lion or tiger.

One of the most characteristic substances found in the urine of herbivora is hippuric acid, which derives its name from the fact that it was first discovered in the urine of the horse. Under ordinary circumstances this acid exists in quantity at times equal to that of the urea.

2. *Birds*.—The urinary excretion of birds, as far as my observations go, is semi-fluid, cream-like, and very rich in uric acid. As much as 90 per cent. of uric acid, or even more, has been found in it, together with a varying quantity of ammonia. I have always found it distinctly acid in reaction, whether the bird was living on meat or grain.

3. *Reptiles*.—In so far as the eye can discover, or as chemical analysis has succeeded in making out, the urinary excretion of ophidian and saurian reptiles is identical with, or most closely resembles, that of birds. I have carefully examined that of several pythons, boas, cobras, and the common English snake; also of various saurians, as the Australian monitor, etc. Urea is said to be absent. In the chelonian reptiles the excretion differs from that of ophidians and saurians, in being almost liquid, usually consisting of a clear watery fluid, containing opaque white flakes of urates.

4 and 5 *Batrachians and Fish*.—With regard to these classes of animals but little information has as yet been obtained.

6. *Invertebrata*.—Lastly, one word as to the nature of the urinary excretion in the invertebrates. With the exception of animals belonging to the class arachnida, as the scorpion and spider, which excrete guanine ($C_4H_5N_5O$), a substance found in guano, and probably derived from uric acid, and closely related to it in composition, all the invertebrata throw out uric acid or urate of ammonium.

Having now given a short sketch of the character and composition of the urinary excretion of the different classes which compose the animal kingdom, we are naturally confronted by the question: Why this difference in the excretion of nitrogen? why in some animals does it chiefly take the form of urea, in others that of uric acid? The supporters of the first view have attempted many explanations, the favorite one being that it depends on the greater or less activity of the function of respiration. Liebig pointed to the fact that mammals, having a high temperature and active respiratory function, throw out but little uric acid and a large quantity of urea; whereas reptiles, with a low temperature and a correspondingly low respiration, throw out their nitrogen chiefly as uric acid. This view was founded on limited data, and we have only to turn to the large class of birds for its refutation. Here we see animals with the highest temperature and a respiration correspondingly active eliminating their nitrogen in exactly the same form as the cold-blooded reptiles.

The nature of the food taken has been thought by

many to have a powerful influence on the excretion of uric acid, but it needs very little consideration to show the inaccuracy of this idea; for ophidian reptiles, as the python and boa, which live exclusively on animal food, and grain-eating birds, such as the canary and others, whose food consists entirely of seeds, excrete the same nitrogenized products; in fact, it is difficult to separate the urinary excretion of the one class from that of the other, as I have already stated, both consisting of uric acid in combination with some ammoniacal compound. Again, if we compare a toad with a lizard, the little influence of the character of the food is at once strikingly shown: both animals live on flies, yet the urine of the toad is clear and watery, and contains no appreciable uric acid; whereas that of the lizard resembles cream, and consists mainly of urate of ammonium. The excretion of uric acid and of urea also is doubtless much influenced by the amount of food taken, whether in the same ratio has not yet been determined.

Some physiologists look upon the spleen as the producer of uric acid; others regard the liver, some the lymphatic glands, and some the cartilaginous tissues, as the originators of this principle. But there is one fact which must not be lost sight of—viz., that whether an animal throws out all its nitrogen in the form of uric acid, or in that of urea, it, equally in either case, possesses a spleen, a liver, lymphatic glands, and cartilaginous tissues.

Of course, if we accept the second theory, and regard the kidneys as the producers of uric acid, the difficulty of the question is at once solved; we have only to regard the kidney as containing different cells; some, perhaps, for the formation of urea; some, at least, for the production of uric acid, and to hold that the number of the latter cells, compared with the other excreting cells of the kidney, differs in different classes of animals.

Let us pass on to another point in the physiology of uric acid. How can we explain the fact that, in proportion to the weight of their bodies, some animals excrete so large a quantity of such an insoluble principle as uric acid, or even as urate of ammonium, the one requiring 8,000, the other 2,400 times its weight of water at the body temperature to dissolve it? The human subject excretes, on an average, in the twenty-four hours, about one part of uric acid for each 120,000 parts of his weight, or, estimating the weight of a man at 10 $\frac{1}{2}$ st., throws out about eight grains of this acid daily. In the case of the lower animals, I could find no facts on record relating to this subject, and therefore had to undertake to supply them for myself by means of the following observations and experiments. I had a cage constructed, with a glass floor, so as to be able to collect the whole of the excreta of the twenty-four hours from the bird that occupied it, and from such I carefully ascertained the quantity of uric acid: no difficult process.

1. A canary bird was kept in the cage, its food consisting of a supply of canary seed, millet, and hemp, together with water. In twenty-four hours I found that the excretion of uric acid was 2.1 grains and the weight of the bird was 277 grains, so that the ratio of the uric acid excreted in twenty-four hours to the weight of the bird itself was 1: 132.2.

2. An Australian grass parrakeet was next kept for twenty-four hours in the same cage, and fed on the same food. The weight of the excreted uric acid was 3.1 grains, that of the bird 415 grains. The ratio of the uric acid to the weight of the bird was 1: 133.8.

Had I calculated the weight of the bird from the weight of its excreted uric acid, taking the ratio in the case of the canary for my standard, I should have estimated the weight of the parrakeet at 409 grains instead of 415. The observation was repeated with a second parrakeet of the same weight, and the same result was obtained—viz., 3.1 grains of uric acid in the twenty-four hours. Let us, then, take 1: 120 as a fair ratio, including in the calculation both carnivorous and graminivorous birds, and we arrive at the somewhat startling conclusion that the bird in proportion to its weight excretes 1,000 times more uric acid than man.

In pursuit of this subject, I made further observations on the relation between the daily weight of the uric acid excreted and the weight of the renal organs themselves. In the case of a lark I found that the ratio of the weight of bird to that of kidneys was 125: 1; in that of a linnet, 118: 1. Taking the lark and linnet therefore, after calculating their daily excretion of uric acid, we find that it amounts to more than the weight of the kidneys of the same birds. Let us reflect on these facts. Is it possible to conceive, if we assume that the uric acid first exists in the blood, that the amount of this fluid passing through the renal organs could excrete as much of this principle as we have found, as a fact, to be thrown out? True, in the case of man, who excretes only one-thousandth part of the uric acid thrown out by birds, we could easily imagine this to be the process, but the more we consider the facts about birds, the more difficult does it become to believe in this explanation, and if we go further and hold it impossible, then the first view as to the formation of uric acid appears to me to fall to the ground.

As this question is of the utmost importance to physiology, and as its decision must necessarily be followed by weighty consequences, it is essential that nothing should be left undone which might help us to the truth. With this object before us, there arise many points which must be determined, and, first of all, we must ascertain the condition of the blood of various animals, especially with regard to the presence or absence of uric acid. I have obtained many such data from observations made during a long course of years. I have several times examined the blood of man in health, and many hundred times in various diseases, and the conclusion at which I have arrived is this: that in absolute health the uric acid in the blood is inappreciable by our tests, and that that fluid does not contain the 100,000th part of its weight of the acid, while in gout the blood is very rich in this principle, as I showed in 1847: that uric acid is also found, in much smaller but still appreciable quantities, in individuals who are developing a gouty condition, or who are under the poisonous influence of lead.

In the blood of various other mammals, as the ox, sheep, and pig, I have never found a trace of uric acid by the uric acid thread test. I have also examined the blood of several species of birds, as the turkey, common fowl, pigeon, and duck, repeatedly in some instances, and have found it as free from uric acid as that of the mammal.

The result of these observations must be looked upon as somewhat striking, and even startling, to those who regard the uric acid in the urine as simply a filtration from the blood, when we remember that the blood of birds, whose urinary excretion is almost entirely composed of uric acid, is as free from that principle as the blood of the herbivorous mammal, in whose urine it is usually difficult to detect a trace; or, again, that the blood of the bird is as free as, and often freer, than that of man from uric acid, though it excretes daily about 1-120th of its own weight of

that principle, man eliminating not more than 1-120,000th.

Let us go a step further in the inquiry, and let us assume, for the sake of argument, that the blood of a bird contains, which it certainly does not, 1-50,000th of its weight of uric acid, a quantity which, if present, could easily be detected by my so-called "uric acid thread test," and let us make a rough calculation of the quantity of blood which passes through the kidneys in the twenty-four hours. The figures contained in the table may be regarded as sufficiently correct for the purpose of illustration.

I assume the weight of the bird to be represented by a certain figure for convenience sake, and all the appended numbers have relation to that number.

TABLE (*illustrative only*).

	Grains.
Weight of bird.....	277.0
" heart.....	4.0
" kidneys.....	2.5
" blood in body.....	23.5*
" uric acid excreted in 24 hours.....	2.1
" blood thrown from left ventricle at each beat of heart.....	1.0
Pulsations of heart in 24 hours (120 per minute) 172,800	
Weight of blood passing through kidneys at each beat.....	0.10(?)
Weight of blood passing through kidneys in 24 hours.....	17,280

* Calculated at 8.5 per cent. from starling.

Assuming that one-tenth of the blood that leaves the left ventricle at each beat passes through the kidneys, in which case nearly 7,000 times the weight of the organs would pass through them in twenty-four hours, then the whole of that quantity would not contain one-sixth part of the uric acid excreted during the same time by the bird. We have, in this illustration, given every possible advantage to the supporters of the first theory, for we have assumed not only that what I should imagine to be a most abnormally large amount of blood passes through the kidneys, but also that the blood contains a much larger quantity of uric acid than is really the case. Add to this that we have assumed in the calculation that no trace of uric acid escapes filtration in every passage of blood through the renal vessels—a most improbable assumption. We shall soon have occasion to see what the filtering powers of the kidneys really amount to; in other words, how much uric acid they can excrete from a blood which is known to be rich in that principle.

Our next point is to ascertain what takes place when uric acid, in the form of one of its salts, is administered by the stomach or injected into the blood. In 1849 I gave urates of ammonium, sodium, and potassium with the following results: A man was passing on an average 8.07 grains of uric acid in the twenty-four hours, taking no drug. Urate of potassium was given, in five-grain doses, three times a day; the dose was afterwards increased to ten grains. During the time he was taking the urates the average excretion of uric acid was 8.25 grains—i.e., practically the same as before. I find appended to this case a note of no little interest—viz., that during the administration of the urates the man, who had some eczema, experienced a great increase of skin irritation, which subsided on their discontinuance. This goes far to prove, first, that the substance was absorbed into the blood, and, secondly, that some forms of eczema are closely connected with the presence of uric acid in the blood. To another man I gave, at

first urate of sodium, and afterwards urate of ammonium in doses of fifteen to thirty grains, without the slightest detectable increase of uric acid in the urine.

Subsequently Wöbler and Frerichs found that when urates of potassium and sodium were taken there was an increase of the urea, and a sediment of oxalate of calcium in the urine, but no augmentation of the uric acid. Neubauer found that in rabbits the exhibition of large quantities of uric acid was followed by a corresponding increase of the excreted urea, but no uric acid was discovered in the urine. The injection of urates into the veins was followed by the same negative result as ensued when uric acid was given by the stomach.

If the kidneys act merely as strainers off from the blood of the uric acid brought to them by that fluid, how can we explain these facts? Is it not impossible to do so? If, however, we regard the kidneys as the producers or manufacturers of uric acid from matters brought to them by the blood, then all difficulty with respect to the facts above mentioned vanishes, and we see at once why the amount of uric acid has no necessary relation to the character of the food, but depends on the activity of the formative cells, and the quantity of pabulum brought to them in a given time.

Before we proceed to discuss another point in the physiology of uric acid you must allow me for the moment to assume, what I shall afterwards have an opportunity of proving, that in the kidney cells this acid exists combined with ammonia, or, at any rate, with a base yielding ammonia, and not with any fixed base, as soda, potash, or lime; but that when it is found in the blood, or deposited in the tissues, either of man or the lower animals, it is in the form of urate of sodium. As far back as the year 1847, when I first found uric acid in the blood, I proved that it was in the form of the soda salt.

A few years ago an interesting case of this sort came under my notice, which, as it strikingly illustrates the question which we are now considering, I will relate as concisely as possible. An Australian grass parakeet, which had been quite recently imported, came into my possession and, within a few weeks of its arrival, I found on the digits of its claws little white nodules or protuberances, most of them larger than a pin's head. The bird soon sickened and slowly died. It was afterwards found that each of these nodules contained a cheesy matter, which, under the microscope, exhibited the appearance of being made up of innumerable very fine needle-like crystals, polarizing light with great intensity, and, when chemically examined, yielding an abundance of uric acid, but no ammonia. When incinerated, it yielded the characteristic soda ash. The deposit was, therefore, composed of urate of sodium. It was afterwards discovered that not only were the digits of the claws studded with this matter, but that it extended along the shaft of each leg, and there was a long rod of it in front of the cervical vertebrae, behind the trachea.

Let us now see how these facts can be explained on one or other of the two theories of the formation of uric acid. On the first, it is not difficult to suppose that uric acid may be formed, either in that shape or as urate of sodium (at any rate it would exist in the blood as the soda salt), and become deposited, under certain circumstances, in different organs and tissues of the body; but then comes the difficulty of explaining how it is that it is thrown out by the kidneys combined, not with soda but with ammonia. I cannot conceive any satisfactory explanation under this theory. I know of no chemical conditions which would render such a change possible and would cause

urate of sodium to be filtered through as urate of ammonium.

Let us now, for a moment, adopt the second view and assume that urate of ammonium is produced in the kidneys, and that it sometimes becomes resorbed (the word, though uncommon, is the best expression of the process) into the blood after its formation. How is it that it then becomes changed into urate of sodium? There is no difficulty here, for I have shown that, when urate of ammonium is added to a solution containing a large excess of either phosphate or chloride of sodium, it is converted into urate of sodium, and will crystallize out as such. All difficulty, therefore, as to the explanation of the change in the salt as it passes from the kidney cells into the blood is at once removed, and it necessarily follows that the tissue-deposits which occur in disease must be composed of urate of sodium. As I have already said, those who consider that uric acid is formed before it reaches the kidneys usually look to some other organ as its source—e.g., the spleen.

If the spleen is the organ in which uric acid is formed, why should not this acid be present in the urine of herbivorous as well as carnivorous mammals? On the same assumption, should we not expect that uric acid would exist in much larger quantities in the spleen of animals whose urinary excretion consists mainly of that principle than in others whose urine is often devoid of it? As far as my experiments go, the very reverse is the case, for while uric acid was easily detected in the spleen of the ox, in that of the bird it was most difficult to discover it. Again, it would naturally be expected that in animals that throw out uric acid the spleen would be larger, proportionally, than in others, but I am not aware that such is the case. It must also be remembered that uric acid has been asserted by different observers to be present in other organs besides the spleen, as the liver, lymphatic glands, and brain.

Assuming that our second view is correct and that the kidneys are the true formative organs, then an explanation of the presence of uric acid in the spleen, liver, and other parts is not difficult. When, from any cause, there is an appreciable back-flow of uric acid from the renal organs and resorption, then the blood becomes more or less impregnated with that principle, as we find to be the case in disease, and, under these circumstances, it is attracted by various tissues and becomes united with them. May it not be the case that, when uric acid exists in the blood, it is attracted differently by different organs, and thus the spleen and liver more frequently contain appreciable quantities than other tissues? Or, again, may it not be that in some organs, as the spleen, the substance of which, if not acid during life, rapidly becomes so after death, while the blood remains strongly alkaline, the uric acid becomes less soluble and more easily retained?

Before concluding this, the purely physiological part of our subject, I will state that there are a few facts which demand full explanation under any theory which claims to be accepted as the true one. For instance, the urine of the sucking calf and of the young of other herbivora contains uric acid in notable quantities, while that of the adult animal is usually free from it. How can this be reconciled with the view that uric acid is formed in the kidneys? There are also other facts closely allied to these which appear to be equally difficult of explanation by the second theory.

In the course of these Lectures I hope to be enabled fully to solve these difficulties, and, in so doing, to bring before you many observations, the results of which may prove to be of great service and value both in pathology and in therapeutics.

Original Papers.

THE ETIOLOGY OF DIPHThERIA, THE NATURE OF ITS CONTAGIUM, AND THE PHENOMENON OF SUDDEN DEATH OCCURRING IN IT, RECONSIDERED.

By EDWARD WOAKES, M.D.,

Senior Aural Surgeon, and Lecturer on Aural Surgery, at the London Hospital, Senior Surgeon to the Throat Hospital, London.

THE views put forward in the following communication not being in accord with those generally received on the subjects of which they treat, may I venture to solicit for them the considerate attention of the reader on the following grounds? First, because, though briefly summarized, they represent the outcome of many years' careful observance of the disease, under circumstances not unfavorable to its study. Secondly, because I have brought to bear upon the solution of the problems at issue a principle new in its application to such questions. This principle I had the honor of submitting in detail to the medical section of the International Medical Congress held recently in London in a paper discussing the evidences which support it, as well as some of its bearings on the determination of the phenomena of disease. The principles upon which the chief points attempted to be established in this communication rest may be briefly stated as follows:—1. The afferent fasciculi of a given sympathetic ganglion (which are usually found accompanying the sensori motor nerves, being contained within their sheaths) are in reflex relationship with the efferent vaso-motor nerves furnished to the arteries from the same ganglion. 2. That the medium of this reflex relationship is the particular ganglionic centre with which the afferent and efferent fibrillæ alike communicate. 3. That afferent impulses transmitted through a sympathetic ganglion take effect upon the walls of the bloodvessels supplied by it with vaso-motor nerves, and by enlarging or contracting the calibre of these vessels, produce alterations of nutrition, or of function, in the areas to which the vessels so innervated are distributed. 4. That in this way the sympathetic ganglia constitute centres for correlating widely separate tracts of tissue, bringing them into mutual interdependence in regard of such operations as come within the sphere of their functions. 5. By means of this correlating faculty the sympathetic ganglia are found to be largely instrumental in determining the localization of morbid symptoms. It is to this coördinating function of the sympathetic centres that I appeal in attempting to elucidate those aspects of diphtheria discussed in the present paper. One of my earliest experiences of diphtheria occurred about the year 1860, just after the appearance of Bretonneau's second memoir. The patient, a middle-aged female, was treated with calomel, as recommended by this author, though to a much less extent than practiced by him, and recovered. The case, though well characterized, was not, comparatively speaking, a severe one. During the subsequent fifteen years over which my experience of the locality where this case occurred extended, it was repeatedly visited by the disease. During the latter part of this period I was afforded, in the capacity of medical officer of health for the district, every opportunity of investigating the conditions under which it made its appearance. Two conclusions respecting the causation of diphtheria gradually took shape in my mind, as year after

year it presented itself under very varying circumstances.

The first was, that while I was never able to connect an outbreak of the disease, either in its single or multiple forms, with anything of a distinctly zymotic nature—understanding by this term some subtle poison introduced from without—yet I was nearly always able to connect the cases with some precedent climatic condition or state of the weather. These antecedent conditions were frequently quite dissimilar, comprising periods of intense cold, prevalence of very high summer temperature, long prevailing east wind, or a continuance of cold and wet. It was after such states of atmospherical environment, and not during them, that the disease made its appearance.

Secondly, I observed a very decided proclivity on the part of certain families to take the disease. By this I mean, there were some families in which, when the disease occurred, it usually ended fatally as regards the first subject attacked; it had a greater tendency to spread in such families than in others from one member to another; and finally, whenever a future outbreak appeared, these families would be nearly certain to contribute further examples of it. I have followed such families in different houses, have carefully examined their sanitary arrangements, but never found anything to which the attack could be traced, beyond those climatic influences already referred to. Almost invariably the children were healthy-looking subjects of the respectable middle class, but there was about them usually a softness of texture approaching to flabbiness, which seemed to betoken a want of tone in their constitution.

Concerning the *modus operandi* of these predisposing causes of diphtheria, two inferences were arrived at—viz., the climatic conditions above described constituted an exhausting influence to the subjects exposed to them—i.e., a great demand was made on the vital energy in order to resist their effect, and that this was equivalent to a withdrawal of nerve force from the system. Further, that young growing subjects who needed all their *vis viæ* for the purposes of their own economy, were most easily drained of this force. Secondly, the circumstance that some families exhibited a greater readiness than others to part with this force was probably due to inherited mobility of vaso-motor centres—a subject interesting on its own account, but which cannot be further discussed on this occasion.

In order to localize more specifically the processes brought into play by these proximate causes, it is necessary to assume for a moment, what I trust will subsequently be evident, that the exhaustive drain on the vital forces of the system induced by the foregoing causes, takes effect chiefly on those nerves and nerve-centres which are concerned with the nutritional functions. In other words, it is the vaso-motor nerves and their centres that suffer most from the paralyzing influences to which the subject has been exposed.

Having premised thus much, the next step to consider is the immediate or exciting cause of the attack. In this connection it is necessary to give unreserved attention first of all to the large group of cases which occur singly—in isolated situations often—and where, so far as it is possible to ascertain this point, the subject has not been exposed to any cognizable contagium. In considering this important feature of the disease one is struck with the fact that this aspect of it—viz., its possible spontaneity of origin—has not met with the attention it deserves. I propose therefore to examine it from this point of view, conceiving it possible to show how, by the derangement of a certain mechanism of the economy, a true diph-

theria is capable of developing itself *de novo*. Take, for this purpose, an already prepared subject—that is, a young, growing child, who has recently undergone exposure to severe climatic surroundings, and whose vital powers have been already exhausted by these—imagine him exposed to a chill, so that in some way or other he takes cold. What I understand by this expression is that a draught of cold air, impinging upon the unprotected surface of the patient, imparts a shock to the afferent sympathetic nerves accompanying the cutaneous branches of the cerebro-spinal nerves to the skin. This is conveyed along the afferent channels to their centre, whence it is reflected efferently to the correlated vessel nerves with which the centre associates them, as a wave of vessel dilatation. Under the circumstances detailed, of already exhausted vaso-motor force, this last shock implies a more or less complete paresis of vessels distributed to a particular area.

For the sake of anatomical brevity we will suppose the foregoing afferent impulse to be received by that portion of the upper cervical ganglion which contributes the *nervi molles* to the external carotid and its branches. The efferent response, so far as it implicates mucous tissues, will manifest itself in the vessels supplying the nasopharyngeal and laryngeal areas. Such a state of things may with reason be said to happen every time a cold in the head occurs, when vessel-dilatation expresses itself in congestion and effusion—in other words, catarrh—which may be nasal pharyngeal, or laryngeal, or all combined. But there is no more generally admitted fact than that a catarrhal condition is the frequent precursor of diphtheria. My contention is that the particular pathological state exhibited by the affected region has reference solely to the degree of pre-existent vaso-motor paralysis. For if the process end as catarrh, it implies that the patient was previously in ordinary health as regards his nerve-power, when the rebound from a state of vessel dilatation to one of equilibrium is rapid and complete.

If, then, we regard the catarrhal state as the mildest expression of vessel paresis, as it manifests itself in this region, a still more advanced degree is witnessed in phlegmonous sore-throat, where oedema is the prevailing symptom. It indicates that the subject has undergone a prior drain of nerve force. How closely it approximates to the diphtheritic condition, in respect of its parietic accompaniments, will be evidenced shortly. Whether this point of passive congestion with oedema can be exceeded is a question only of inhibitory resource. If this latter be exhausted, as in the case before us, the extreme stage of the process is reached, and plastic exudation results. In this supreme degree of vessel dilatation the most prominent feature is the astonishing generative activity of cell elements. Doubtless the suddenness with which the tissues are invaded, after the patient has received the final and determining shock, exercises an important influence in deciding the character of the processes about to supervene. The pre-induced recuperative incapacity of the vaso-motor centres, which is the true element of malignity in the disease, is by this last circumstance concentrated as regards its vessel influence on a region having a superficial situation, and of slight depth of tissue. Any vigorous process lighted up in it will rapidly tend to appear on the surface. That which is now at work implies the incursion of the transudation corpuscles from the vessels into the sub-epithelial layers, exciting into rapid growth and multiplication the connective-tissue corpuscles, and also some very special cell strata abounding in the pharyngeal walls. Richly supplied with albuminoid pabulum from the same

source, these rapidly growing germs crowd towards the point of least resistance, and are checked in their surfacewards career by the as yet intact basement membrane. At this point they become more plastic and organized in their character, and, getting incorporated with the limiting membrane, present to the observer the pathognomonic characters of the diphtheritic pellicle.

Thus far the tendency of my argument is to lift diphtheria out of the sphere of blood poisons, and to restore it to the rank of ordinary inflammations, where presumably Bretonneau located it, and to which all its analogies as seen from my point of view tend to affiliate it. That the disease is not limited to single occurrences, and that when established it may be propagated by contact, are facts which will doubtless cause many to hesitate in accepting the foregoing conclusion.

Respecting the *contagium* of diphtheria, it is necessary to remark that it is not an indefinable something, foreign in its origin to the human economy, but that it is a definite tissue element normally present in the body, a constituent part of it, but altered as regards its capabilities by the newly acquired conditions under which it is thrown off.

With regard to this normally existent tissue element it is to be observed that in almost every locality where mucous membrane subserves a special function, it is characterized by some peculiarity of structure which is more or less individual to it. This statement does not ignore the fact that it may possess structures common to every other part, or common to it as well as some others only. To mention one peculiarity of tissue belonging to the region of mucous membrane most obnoxious to diphtheria—that of the fauces—Luschka has described and figured a certain stratum of lymph corpuscles seated below the epithelium in the connective tissue, about midway in the depth of this latter structure, and most abundant in the posterior wall of the pharynx.

The contention of my argument regarding the special *contagium* of diphtheria is as follows. Either this cell-stratum of Luschka or some other developmental cell structure belonging to the affected locality undergoes that alteration in its capabilities already referred to the circumstances of the disease through which it has passed. The nature of this changed capacity is that, having been designed to take part in such slow formative processes as belong to equable growth—the replenishment of normal wear and tear—these cells have been impelled by the conditions of a violent inflammation to compress into the space of a few hours the developmental energies they were designed to exhibit only through the progress of years. Thus, started into activity by a superabundance of nutritional supply, and accelerated by a vast increment of heat, they rapidly multiply in number as they approach the surface, die, and are shed; their life history is played out before they could become incorporated with structures of which they were designed to form integral parts. This hot "riot" of cell life and death, taking place as it does quite near the surface, the process of shedding will be a rapid one, and many cells will escape that have not yet completed the rôle of growth which ends in destruction. Many will have started only on their course; others will be more advanced; and when set free from their surroundings, it requires only their transference to a suitable soil to enable them to complete the process already commenced. Neither have they lost their structural affinities. A paramount condition of the completion of their energies is that they be conveyed to such a tissue as complies with the histological relationships of their original situa-

tion. Once replanted in such congenial soil, these rapidly growing cells are not only capable of completing their own development, but also of exciting a corresponding premature activity on the part of the analogous structures with which they are brought into contact. On the degree of vessel-response to the tissue demand for more pabulum to satisfy the new process depends the character of the inflammation now established. This resolves itself into a question of amount of vaso-motor inhibitory force with which the centre receiving the demand is able to meet it. Obviously the intensity of the process will be proportioned to the prior depletion of vaso-motor energy which the subject has already undergone. Accordingly, these growing cells, cast off as above described, are potential diphtheria germs; and if the patient to whose analogous tissues they are transferred present the required state of vessel paresis, they become *de facto* capable of generating the disease in the subject so receiving them.

It is of great service to recall here what happens when the individuals who entertain these germs have not experienced the preparatory depression necessary to constitute what I now venture to call the diphtheritic diathesis. The experience of every family physician will enable him to substantiate my statement that nearly all the adult occupants of a house where diphtheria is rife, and who are brought within reach of the *contagium*, do suffer from sore-throats. But these, in the cases now referred to, are not diphtheritic throats. They are simply inflamed, often severely so, and may even exhibit the cedematous type. Thus, I have many times seen the parents of diphtheritic children, also the servants and nurses attending them, successively fall ill with attacks of faucial inflammation of varying degrees of intensity. So much is this the case that one may not infrequently witness in the different members of the same household the three phases of catarrhal, phlegmonous, and diphtheritic sore-throats at one and the same time.

This circumstance appears to me to have the value of a crucial experiment, tending directly to support my position, because the facts of the case leave no room for doubt that the exciting causes of these simple inflammatory attacks are the emanations of the original diphtheritic patient. Now, if there is anything specific in the nature of the diphtheritic germ, it is contrary to all analogy, as well as to all experience, that it should excite one disease in A and another disease in B. The obvious inference, indeed the only logical one, is that the element of specificity resides in the subject, and not in the germ. This specificity is, as is already stated, the inability on the part of the patient to resist the requisite blood-supply necessary to feed the germ-excited tissues to the diphtheritic point; it means the loss of vaso-motor control over the vessels implicated, and is the direct outcome of previous subjection to an exhausting environment. Respecting the possibility of croupous or diphtheritic membrane being formed spontaneously—i.e., idiopathically—the following apposite quotations should be noted:—

Billroth, "Surgical Lectures," p. 100, says that in large wounds, especially in fistular granulations, a yellow rind sometimes forms on the granular surface, and is readily detached. It consists of pus cells very firmly attached together. "Although I have sometimes found coagulating filaments between the cells, they do not always occur; hence we must suppose that the cell-body, the protoplasm itself, is transferred into fibrine, as occurs in true croup, and especially in fibrinous deposits on serous membranes. Under favorable circumstances it may result in destruction of the granu-

lations, in a true diphtheria of the wound, to be treated of hereafter as hospital gangrene. Usually croupous inflammation of a wound ends in sloughing of the diseased granulations, whereupon new ones spring from its depths." Virchow's view of croupous inflammations generally is that by the inflammatory process the tissue may be placed in a condition to cause coagulation of the fibrinous solution infiltrating it. According to A. Schmidt, in certain quantitative and qualitative irritations of the tissue, more fibrogenous material than usual escapes from the capillaries. Virchow has shown that by repeated irritation simple serous exudation may become fibrinous or croupous, as when by repeatedly blistering a previously healthy surface, it becomes covered with a fibinous layer, which is almost entirely composed of newly formed cells. Cognate to this evidence adduced from a wide range of analogies by authors well fitted to judge of their pathogenic meaning, is the case of a lady in whom a true membranous croup was rapidly induced by the accidental ingress of eau-de-Cologne into the larynx through the left nostril, to which it was applied while the patient was in a fainting condition. The case is recorded p. 95 *et seq.* of the "Report of the Committee of the Royal Medical and Chirurgical Society on Membranous Croup and Diphtheria." On the fifth day, ninety-two hours after the accident, "a perfect cast of the larynx, trachea, and upper part of the left bronchus was expelled entire in one piece." Patches of membrane also occurred in various parts of the naso-pharyngeal tract. There was no diphtheria in the neighborhood. Making allowance for the fact that microscopical examination was made some considerable time after expulsion, there were no appearances by which this cast could be distinguished from a true diphtheritic one. Such exudations, when occurring in the closed sacs of serous membranes are recognized as the orderly outcome of simple inflammation. The preceding quotations carry out this recognition to tissues of almost every type, while the concluding one brings the connection home to the very seat of diphtheria, inasmuch as it shows a membranous cast to have been formed in the naso-pharynx, larynx, and trachea, by the application of a definite local irritant.

The culmination of the disease in *sudden death* is the last feature to be examined. It remains to show how the adoption of the hypothesis of vaso-motor exhaustion as the essential factor in the causation of diphtheria supplies a constant explanation of this symptom. The phenomenon in question hinges upon the fact that the loss of reflex vaso-motor control extends to the *nervi vasorum* of the nutrient vessels of certain nerves, as well as those of the vessels distributed to the mucous membrane. It will assist its explanation to compare it with a slighter, or penultimate, degree of this latter kind of paresis, sometimes met with in the oedematous phase of throat inflammation, which I regard as occupying an intermediate position between catarrh and diphtheria. As I know of no better example than was afforded in a recent personal experience of my own, I will briefly quote it. In the spring of 1879, when considerably prostrated in health by an attack of influenza, I had occasion to inspect very closely the throat of a patient who was the subject of catarrhal diphtheria, and shortly afterwards was exposed to a sharp easterly wind. The same evening I was conscious of having acquired some severe throat mischief, which in the course of the next day assumed the proportions of what is indifferently termed phlegmonous, oedematous, or hospital sore-throat. Oedema of the epiglottis was an early symptom, quite prohibiting the act of swallowing

by the intense pain occasioned by any attempt to perform it. Forty-eight hours from the commencement of the attack the œsophagus was paralyzed. It showed itself thus: Having endured a fast up to this point an insufflation of morphia enabled me to get down first some beef essence, and then about a tablespoonful of milk. In the course of two or three hours, when the local influence of the anodyne was subsiding, there ensued a sort of cough, easy, and almost effortless, accompanied by expectoration. My astonishment was great to notice that the ejecta consisted first of the milk last swallowed, uncurdled, and fluid as taken, and then the beef essence, also unaltered. Clearly these nutrients had not passed further down the gullet than the space they occupied, as was shown by the fact that they were not mixed nor in any sense changed in character when rejected, which would have been the case had they passed into the stomach. The inference seemed obvious—viz., that there existed a paralyzed state of the lower portion of the œsophagus, which would not allow even fluid food to pass through it. If this conclusion be a correct one, it appears to admit of the following explanation: The plexus *gulsæ* is largely constituted by the *vagus*, augmented by branches from the third segment of the upper cervical ganglion. These nerves were already paralyzed on the second day of the attack in my case. It has already been shown that the local lesion in the fauces was the result of vessel-dilating impulses proceeding from the same vaso-motor centre as contributes the sympathetic portion of the plexus *gulsæ*, but which are distributed upon the vessels of the pharynx and adjacent tissues exhibiting the disease. Other vessels are furnished with sympathetic fibrillæ from the same source—notably those which are the nutrients of the œsophageal branches of the *vagus* nerve itself. These also participate in the dilating waves, and become hyperæmically distended, the result being to strangle the contained motor fibres, and for the time being annihilate their function. The vermicular action of the gullet, which is excited by the presence of food, could not occur in consequence of the nerves being thus rendered incapable of transmitting impulses. Hence the food remained in the œsophagus, the horizontal position being sufficient to cause it to run out.

In the foregoing case the dilator impulse was, fortunately for its subject, limited, not only in point of time over which it extended, but also in the range of nerve ramification which it influenced. For, with the preceding explanation as its clue, it is easy to see what would ensue were the nutrient vessels of the *vagus* more largely involved in it, as is the case in true diphtheria when the exciting cause of the paresis is more intense from the greater exhaustion of the vaso-motor ganglia participating in it. Because, almost the next set of branches of the *vagus* affected in its descensive extension is the cardiac set. When it is remembered that in diphtheria the vessel dilating impulse is bilateral usually—i.e., both *vagi* come under its influence, should this condition of hyperæmia extend to the cardiac branches of the pneumogastric on both sides—it is easy to see that death must ensue from the fact that the heart being cut off from the inhibitory centre will run on at a pace tending to exhaust its contractile powers. And further, that such a cardiac breakdown is peculiarly apt to occur on the sudden rising of the patient from the recumbent position. I am aware that the occurrence of sudden death has long been referred to the *vagi* somehow or other. But the exact how has not been defined. Nor, I contend, is it possible to do so without the application to it of the theory of correlated nerve

tracts. It has been supposed in some way to be an effect of that mysterious and subtle agency the diphtheritic poison, operating through the blood on the nerve centres. But if I am right, the vagus is only implicated in so far as by an anatomical accident, or rather coincidence, this nerve of vital import happens to have its blood-supply regulated by vaso-motor nerves which effereently respond to the original vessel-dilating impulse, affereently exciting the whole phalanx of symptoms. The cardiac branches of the vagus, it will be seen, are not paralyzed centrally, but are only mechanically hindered from transmitting impressions by the sudden afflux of blood, which for the time being abnegates their conductive functions. It is probable that this oppressed state of the vagi is operative to a less extent in all cases of severe diphtheria, and that it accounts for the gradual sinking of the patient, when death is said to begin at the heart; or further, by a similar implication of the pulmonary branches, death may ensue by arrest of the respiratory function. That it is the permanency of the results of this congestion of the vasi-nervorum—i.e., of the resultant effusion within the nerve sheaths, which explains the paresis of the palate muscles, as well as those of other regions, remaining after recovery from the disease, cannot I think be doubted. It is unnecessary further to consider this symptom, as it is foreign to the scope of the present communication. For the same reason I must forego the discussion of the parallel examples of paresis of the muscles of the Eustachian tube and palate, frequently seen as the result of every persistent post-nasal catarrh, though this symptom is of peculiar interest, inasmuch as it tends to establish the complete analogy between the three forms of throat mischief already alluded to.

The length to which this paper has extended compels me to defer entering upon the numerous corroborative proofs of the correctness of the conclusions herein advanced. It will suffice the objects in view briefly to enumerate the inferences arrived at.

1. Diphtheria is an idiopathic inflammation, the peculiar type of which is imparted by previous exhaustion of sympathetic nerve force; that the loss in question occurs chiefly in children, in whom the nutritional centres are normally in special activity; and that this exhaustion acknowledges chiefly climatic conditions possessing in themselves no other peculiarity than is implied in the tendency to lower the vital energy of the subjects exposed to them. The patient so circumstanced may be said to exhibit the diphtheritic diathesis. During its continuance exposure to a slight exciting cause, such as a common cold, will suffice to develop a typical attack of diphtheria. Under these circumstances the disease may be said to arise *de novo*.

2. When the diphtheritic process is established, in whatsoever way it may be brought about, the element of contagium is introduced. Though not, perhaps yet capable of exact histological identification, this is nevertheless a definite tissue element, forced into rapid growth. In this state it is liable to be thrown off with the detritus of the process, and is capable of continuing its developmental energies, and of exciting a similar action in the corresponding tissues of another subject, if it come in contact with these, providing the subject be already predisposed to exert insufficient inhibitory nerve-power to resist the tissue demand for such an accession of blood as will suffice to feed the new process to the diphtheritic point. The latter quality resides entirely in the vaso-motor resources of the patient.

3. The explanation of the symptom of sudden

death occasionally witnessed in the disease is shown to depend on a similar paresis of the nutrient vessels of the cardiac branches of the vagus, as was seen to occasion the local lesions in the throat when affecting the vessels of this area. In consequence of the engorgement of the circulation within the nerve sheaths, and the jugulation thereby of the contained fibrillæ, the latter are unable to transmit inhibitory impressions to the heart, which accordingly ceases to beat after a continuance of rapid action has exhausted its inherent vitality.

Harley-street, W.

TRACTION IN HIP DISEASE, AND THE CONSEQUENCES THAT MAY FOLLOW.

By JOHN JONES, M.R.C.S.

Two years have now elapsed since my former communication on this rare complication appeared in *THE LANCET*, and the time has now arrived when it may not be inopportune to add some further particulars as to the sequel. In any remarks I may have to make, I trust it may not be inferred that I have any wish to detract from the value of traction *per se* in hip disease. On the contrary, in witnessing it for the first time in this case, I was much struck with its simplicity and its adaptation to the purpose for which it was intended. To account for the novelty to me of the traction method, I should add that I retired in 1865, after thirty-eight years' experience of a very laborious country practice (probably before the introduction of the traction method), and I confess from that time I have taken but little interest in what has been going on in the medical world.

The patient at the present time is in excellent health, though pallid (as he ever has been), and backward in his physical development, as a consequence, it may be, of extraordinary mental aptitude. The lameness may be approximately estimated from a shortening in the aggregate of two inches, or but little less than under the old system of treatment. He is equal to any amount of walking exercise with comparative ease, and has no pain or uneasiness in the act or consequent upon it.

I will here give the comparative measurements of the right and left limbs in inches:—

	RIGHT. Inches.	LEFT. Inches.
From the anterior superior process of the ilium to the extreme point of the malleolus internus.....	31	33
From the same point of the ilium to the centre of the patella.....	17½	18
From the centre of the patella to the extreme point of the malleolus.....	13½	15
The fibulæ are precisely the same length on either side—viz.....	14	14

From these measurements it will be seen that three-fourths of the shortening is below the knee, and due to the separation—a striking example of the arrest of the growth of a bone on being separated from its epiphysis. As to the immediate cause of the separation, in the absence of injury or disease to account for it, I think there can be but one opinion, and however rare or remote such a result as happened in this case may appear to be, yet it clearly proves it to be within the range of possibility.

There may have been less power of resistance in the tissues in this case than in others of a kindred

idiosyncrasy, but there was nothing in the aspect of the patient to indicate this. Under these circumstances the question suggests itself whether all the advantages of traction might not be equally secured by placing the fulcrum on the femur, immediately above the condyles, instead of the ankle; it might be thought advisable also in such a case to attach the foot to the cord to prevent inversion.

I have reason to believe that the separation took place at a very early stage of the treatment, for on my first undertaking the charge of the case (owing to the serious illness of the gentleman in attendance) which was in November, 1879, just twelve months after the patient had been under treatment, I noticed an enlargement at the head of the fibula. I was perplexed, and feared there might be some mischief going on in the tibia, but there was neither heat, swelling, pain, nor tenderness, and the attachments of the bone were as firm as ever. The discovery of the separation revealed the mystery, which was nothing more than the continued growth of the fibula, while the tibia remained in *statu quo*.

In my former account I said that I treated the lesion as "a common simple fracture." This I abandoned after a few weeks, and adopted the following more promising method. I had a sandal made for the foot, and a collar and buckle for the femur, just above the condyles. These two points were connected by straps and buckles, which on being drawn up tightly pressed the separated parts together. The parts being so surrounded by ligaments and their aponeurotic expansions, I did not think it necessary to encumber the patient with any bandages against the possibility of a lateral displacement. This method proved highly satisfactory, and there is every reason to think that a perfect anastomosis has been established, as there has been no appreciable shortening of the tibia for the last year and a half, and the enlargement at the head of the fibula remains in *statu quo* (in the opinion of the patient rather diminishing). Lastly, the question suggests itself, Is this case (as it might appear to be from the strong protest of so eminent an authority recorded in my former history of this case) unique? I candidly confess that I do not think so, for reasons that appear in the history of this case alone. It is an interesting question, and one that ought and might very easily be determined, if gentlemen (of whom, no doubt, there are many) who have the means of doing so, would measure the relative length of the crura of a few who have undergone the traction treatment, and would make the result of their inquiries known through the medium of THE LANCET.

Lewes.

ON CERUMINOUS ACCUMULATIONS IN THE AUDITORY MEATUS.

By J. MACKENZIE BOOTH, M.A., M.B.,

Physician to the Aberdeen General Dispensary.

AMONG the cases occurring in the practice of those who devote attention to the treatment of aurial disease, few are more common or generally regarded with less interest than accumulations of cerumen in the external auditory meatus; and this is doubtless owing to the comparative ease with which they are removed, and along with them the deafness, tinnitus, vertigo, etc., with which they are often associated. Yet their etiology, as far as I am aware, is not well ascertained. In the textbooks on diseases of the ear little is said on the subject further than that these accumulations often take place rapidly, and that they result from

over-activity of the ceruminous glands from irritation of the external meatus by means of towels, etc., and often coexist with conditions of copious perspiration, as in the case of the laboring classes.

In the ear and throat clinic of the General Dispensary here three cases bearing on this point have recently come under my notice. They were those of three men of middle age, who worked as brass finishers in the same workroom, in all of whom the accumulation took place about the same time, and in whom the right ear was that chiefly affected. The first came up at the end of December, 1882, complaining of deafness and discomfort in his right ear. On examination the watch could only be heard on contact on the right side, and on the left the hearing was also somewhat impaired. The mirror and speculum revealed a ceruminous plug in both meati, that on the right being the larger, and in great part softer than the other. The use of the syringe soon freed him from his unpleasant symptoms.

A fortnight later No. 2 appeared, complaining of deafness, tinnitus, and uneasy sensations in his right ear. In this case, too, the watch was only heard on contact on the right side, while hearing on the left side was normal, and a ceruminous mass was syringed out, giving him relief. The mass, which came away in pieces, I noticed had green specks in its substance. The left meatus was normal.

In the end of January, 1883, the only remaining workman in the same shop, No. 3, presented himself with deafness and tinnitus in his right ear and occasional giddiness. As in the case of the others, the unpleasant symptoms were disposed of by the expulsion of a large quantity of ceruminous debris intermingled with greenish specks. The fact of this being the third case from the same place within a short space of time made me examine the patient more carefully, and also the quondam contents of his meatus. The naked eye readily detected small greenish specks of "verdigris," and under the microscope a low magnifying power showed a number of fine metallic particles interspersed through the ceruminous mass.

No. 3 informed me that about three months previously they (the three men mentioned above) had had a good deal of extra work on hand, that they had all perspired copiously, and all suffered from catarrh about the same time. He also stated that their deaf side was the one turned towards their work, which in the process of sand-papering produced a very fine cloud of brass particles.

In these cases the entrance of the brass particles into the ear must have played some part in causing the accumulation, since in two of the cases at least the left ear was free from plugging. The small hard plug in the left ear of No. 1 was probably of much longer standing than the others, which were of larger size and softer consistence. The left ear thus had evidently escaped from not being so much exposed to the metallic shower, otherwise the two ears were under similar conditions. But the entrance of the brass particles alone would not have been sufficient to cause the formation of these plugs, else they would have occurred much oftener in these men working constantly at their trade. All three patients had been working harder than usual about three months previously, and from this they dated the uncomfortable feeling in their ears and the tendency to pick them. This corresponds with the observations of Burnett¹ and others that rapid secretion and accumulation of cerumen are generally concomitant with increased activity of the sweat glands. In the above cases

¹Treatise on the Ear, by C. H. Burnett, pp. 289, 290.

this, however, would not yet have been sufficient to account for the accumulation, as these men were often very busy and often perspired profusely. But at the same time all three had complained of more or less catarrh. And to this along with the foregoing conditions, I would attribute the right-sided accumulations of cerumen. In the treatment of ear cases I have frequently found rapid accumulations of ear-wax following a nasal catarrh, there being only in some of these marked implication of the tympanum or Eustachian tube. The intimate relation of the vascular supply of the meatus to that of the naso-pharyngeal mucous membrane through the various branches of the internal maxillary artery, would lead us to expect increased activity of the ceruminous glands along with a similar condition of the mucous glands of the naso-pharynx, and this I believe, from the observation of many such cases, to be a very common starting-point of ceruminous accumulations in the auditory meatus.

Aberdeen.

NOTES OF A CASE OF EXTRA-UTERINE PREGNANCY (TUBO-OVARIAN); RUPTURE OF CYST; DEATH.

By WM. BERRY, M.R.C.S., L.R.C.P. and S. ED.

Honorary Surgeon, Royal Albert Edward Infirmary, Wigan; and
Honorary Medical Officer to the Convent of Notre Dame, Wigan.

THE infrequency of extra-uterine pregnancy and the obscurity of symptoms, as well as the fatality of the occurrence, have prompted me to send for publication in *THE LANCET* the notes of a case which recently came under my care in the infirmary here. I am indebted to Mr. J. H. Jackson, M.B. Ed., C.M., our junior house-surgeon, for the notes of the case.

Mrs. —, aged thirty-five years, a well-developed woman, of bilious temperament, was admitted to the Royal Albert Edward Infirmary, Wigan, on Dec. 2nd, 1882, with the following history:—She had had four children, two dead-born, and two others which had died in infancy. She had always been healthy, and there was no history of any previous disease. Her husband had deserted her, and left the country five months before, and since she had been in service as a housekeeper. Menstruation had been irregular, and she had suffered severe pain at the menstrual periods, and had been treated for colic just before coming to the infirmary. On examination there was slight tenderness over the right ovary on pressure, and dulness on percussion, and there appeared to be some abdominal enlargement, though this was not very marked. Her bowels were habitually constipated, and she suffered from piles. The heart and lungs were healthy. An enema was administered and the bowels unloaded. Rest was enjoined and warm applications applied. A stomachic aperient mixture was ordered. The temperature was taken daily, and was normal till December 8th, when it rose to 100° F., there being now increased tenderness over the ovarian region.—9th: Temperature, morning 102.4°; a great deal of pain over both ovarian regions. A morphia pill (quarter of a grain) was ordered every three hours, and a diaphoretic mixture; milk diet.—10th: Temperature 102.2°; pain not so severe, but a good deal of tenderness on pressure. On vaginal examination a swelling behind the posterior lip of os could be distinctly felt, but no fluctuation could be made out. The vagina and os uteri were hot and tender to the touch. On the introduction of the sound the uterus was found pushed forward

by the swelling and anteverted, the cavity, however, was normal in length. Ordered pills to be continued and poultices of linseed meal applied, three ounces of brandy daily in soda water to relieve the sickness and feeling of weakness.—11th: A little easier, still tenderness on pressure.—12th: Menstruation came on and the temperature fell to 99°. She felt better and the pain was less.—15th: The temperature remained at 99° till to-day, when it rose to 104° with symptoms of general peritonitis. Ordered salicylate of soda fifteen grains, every three hours, and poultices constantly applied.—16th: Temperature 103°; not quite so racked with pain.—17th: Temperature 101° morning, 104° in the evening. She had a great deal of pain and considerable tenderness on pressure on the right side. Pleurisy and pneumonia could be made out.—18th: Temperature, morning 104°; evening 104.4°; no change.—19th: Temperature, morning 103°; evening 103.4°; pain still severe.—20th: Temperature, morning 101°; evening 102.4°. Vomiting set in, and nothing could be retained on the stomach.—21st, 1 A.M.: Mr. Jackson was called to her; she was in a state of delirium and collapse set in. She died at 7 A.M.

Post-mortem examination by Mr. Jackson, fifty hours after death.—Fluid was found in the right pleura, and red hepatization of lower lobe of lung; heart healthy. On opening the peritoneal cavity a considerable amount of fluid escaped; the peritoneal surface of the bowels was inflamed and adherent in parts. The cavity of the pelvis was filled with clotted blood; uterus somewhat enlarged, and showed signs of congestion; cavity empty. The right ovary was found enlarged, and removed for further examination. Liver pale, other organs healthy. On making an incision into the removed ovary it was found to consist of a large sac from which blood escaped, leaving an embryo an inch long; the eyes, arms, and legs were distinctly visible. The true ovarian tissue did not surround the sac, but formed part of the whole mass outside the wall of the sac. The Fallopian tube could not be well made out, but a small perforation in the sac was visible, through which the blood had escaped into the pelvic cavity. The placenta was well formed and adherent to one side of the sac.

Remarks.—This case is peculiarly interesting, especially as pregnancy was never even suspected. Menstruation had never been absent so far as could be ascertained, though irregular as to time of occurrence, and there was considerable pain before the commencement of the flow. Morning sickness, fulness of the breasts, and malaise were either not present or overlooked. The progress of the case in the wards was peculiar. First we had apparently ovarian congestion or localized peritonitis, then pelvic cellulitis, afterwards symptoms of perforation, collapse, and death. Judging from the size of the foetus, pregnancy had commenced two and a half to three months previously.

Wigan.

ON A CASE OF ADDISON'S DISEASE, WITH MARKED DISCOLORATION OF THE TONGUE.

By LOFTUS WILKIN, M.R.C.S.

JANE W—, aged thirty-two, came under observation on December 28th, 1882. She stated she was one of a family of eight, all of whom as well as her parents were still living, and enjoying good health. The patient has been married for three years, and has had one child, eighteen months ago, which, however, survived its birth only three weeks. She has not suffered from any previous bodily illness, nor from exposure or injury; but

since the birth of her child has been "delicate," and getting gradually weaker, but not sufficiently so to induce her to obtain medical aid. She came down here from the City, where she had previously resided, in June, in order to have the benefit of the country air, and when first seen by me was suffering from severe epigastric pain, which, however, was easily relieved. On examination she appeared to be fairly well nourished; eyes very dark and rather sunken; hair black. The skin presented more or less generally a deep bronze or dusky hue, which was particularly marked about the upper part of the chest, face, neck, and arms, while over the surface of the latter, as on the sides of the neck, were numerous well-defined spots of deep chocolate or almost black color, and about a quarter of an inch in diameter. The gums and inner surface of the lips and cheeks presented a mottled appearance, owing to the presence of numerous patches of a deep brownish or mulberry tint; while on the posterior part of the dorsum of the tongue was one, nearly circular, patch, central in position, and as large as a shilling in diameter; anterior to it, and occupying the right side, was an irregular-shaped patch of nearly equal size; on the left side were two smaller spots, all being of very dark color, almost resembling ink stains while the intervening portions of the tongue were red and natural in appearance. The alteration in her complexion first became apparent to herself and friends soon after the birth of her child, but she did not notice the patches on her tongue till about ten months ago, when they were very small; since then they have been gradually extending, and have attracted considerable attention from herself and husband. Physical examination of the chest revealed no abnormal sounds. There was no cough. No pain or tenderness could be detected on pressure over any part of the abdomen. The bowels were natural. The urine clear; specific gravity 1020; acid; no albumen. Pulse small and weak. She complained of great lassitude and weakness, feeling incapable of getting up; but after two or three days nausea and vomiting set in. This could at first be relieved, but after a time all remedies tried to check it proved ineffectual, in many cases seeming indeed to aggravate it. She was able to retain, however, a fair quantity of iced milk and beef-tea till the termination of her illness. She was put on a mixture containing small doses of solution of arsenic and tincture of steel, but the debility gradually increased. The vomiting became more frequent; epigastric pains and hiccup were occasionally present, but were relieved by an opiate. The pulse at the wrist became imperceptible, the heart sounds very feeble, and she passed quietly away on Jan. 20th, having been only three weeks in bed. Unfortunately, owing to the opposition of her relatives, a post-mortem examination could not be obtained.

Walthamstow.

TWO CASES ILLUSTRATING THE SUCCESSFUL EMPLOYMENT OF THE COLD DOUCHE.¹

By W. H. BROADBENT, M.D.

CASE 1. *Delirium Tremens*.—The patient was a gentleman aged about thirty-eight. His constitution was thoroughly broken by excesses, especially alcoholic, and he had had several previous attacks of delirium tremens. He had been under my care in one of these in November, 1876, which had been ushered in by severe hæmoptysis followed by violent convulsions; and the case had been remark-

able from the fact that the characteristic delirium and tremor returned several times after a long sleep and complete recovery of the mental faculties. The first treatment was by digitalis and bromides, no alcohol being allowed, but beef-tea being given freely. In four days there was sound sleep, out of which the patient woke apparently well. The symptoms, however, gradually returned, and on the third day he was as bad as ever. The bromides and digitalis were again given, brandy being now added to the beef-tea, on the supposition that the relapse might have been due to absence of stimulants when the patient's strength was reduced by loss of blood. There was little apparent improvement, and chloral was given with the bromide, when at length sleep was procured. A relapse followed even more promptly than before, upon which morphia was administered subcutaneously, in doses of half a grain. Again sleep was obtained, with apparent recovery, but all the symptoms returned, and twice more was this recovery under morphia and subsequent relapse repeated. I now took advantage of the first moment when such a proceeding could be considered safe, and took the patient out with me. I made him name all the streets we passed through, kept his attention constantly occupied, and when I had to make a visit told the coachman to keep moving, so that he could not leave the carriage. He always had a story to tell when I rejoined him of two women who had been with him "fighting like the devil," and in his imagination we ran over and killed scores of children. However, he slept after the drive, and afterwards he was sent out daily with the nurse in a carriage till he was quite well. I was called to him again on Dec. 6th, 1878, and found him suffering from severe delirium tremens, which had been carried on for some days. He was well plied with beef-tea, had digitalis and bromides in full doses, and, finally, with great reluctance, morphia in grain doses subcutaneously, without effect. On the night of the 9th he was in a condition of extreme exhaustion, the face pale and haggard, the eyes wild, the skin bathed in perspiration, the pulse soft and small, frequent and irregular. He was almost too feeble to turn his head to follow the images of his fantasy, but was constantly muttering and exclaiming, while his fingers fidgeted with the bedclothes, and every limb, or almost every muscle, was the seat of jactitations. Dr. W. A. Smith, now of Newport, Essex, remained with him all night, and on the morning of the 10th reported that there had been no sleep, and no cessation of the mutterings and jerking, and that two or three times he thought he was dying, the pulse having become imperceptible, the countenance livid, and the voice almost inaudible. It was obvious that the nervous system would not respond to drugs of any kind, and that unless it could be roused by some means or other the patient had not many hours to live. I resolved, therefore, to try the douche. Ice-cold water was brought, and a large bath sponge; the patient was stripped to the waist, arrangements were made to protect the bedclothes, and then the sponge, as full of water as possible, was violently dashed against the head, face, neck, and chest. This was done two or three times, the skin being quickly and roughly rubbed dry between with a coarse towel. I will not attempt to describe the gasping and sputtering and impotent swearing. The process was repeated on the back, and the patient then being made comfortable was told to close his eyes and go to sleep, my hand being firmly placed in his. This he did at once, but in about five minutes he awoke, apparently disturbed by the jactitations, which continued to be violent. He was obviously better, the pulse more full, firm,

¹ Read before the Medical Society of London, March 5th, 1883.

and regular, while the face had warmth and color. During the few minutes of sleep the perspiration could be seen to form drops on his forehead, and roll off almost in a stream. He could not be made to go off to sleep again, and as his agitation increased, and he employed his renewed strength in struggling and shouting, the douche was again administered as freely as before, and he was afterwards commanded to keep his eyes shut, and go to sleep as before. He obeyed, sleep came almost instantaneously, and, in spite of the jerking of the muscles, lasted three hours. On waking up this time he asked where the doctor had got that water from, and was there any more like it. If there was he would have it used again. Used it was by Dr. Smith energetically, after which the patient slept continuously for twenty-four hours, only waking to take food. Convalescence followed quickly and satisfactorily. Delirium tremens seems to have gone out of fashion, and I have not seen a case since this.

CASE 2. *Sleeplessness and Pyrexia after Childbirth.* I was called on the evening of June 3rd, 1881, to see a young married lady who on May 30th had been confined of her first child. The labour had been prolonged and severe, the perineum had been ruptured, and the bladder paralyzed. From the setting in of the labour, and it was said a day or two before, there had been no sleep whatever. I was detained, and did not reach the patient's house till 11.30 p.m. She was under the care of Mr. Ord, of Streatham-hill, whom I met in consultation, and who gave me the above account of the case. Besides the sleeplessness there were pyrexia and severe abdominal pain with great tenderness in the left iliac fossa. The temperature on the previous evening had been $104^{\circ}5'$, on the morning of the day on which I saw her 104° , and at the time of my visit it stood at $104^{\circ}2'$. The patient complained of severe pain in the head, was restless and tossing herself about in bed, the face flushed, the eyes bright, the expression wild and anxious, the skin perspiring everywhere, the pulse 120, and the milk was suppressed. On examining the abdomen it was found to be full and large, but not tense, and the respiratory movements of its walls were not arrested. There was great tenderness over the left iliac fossa, but it was complained of on slight contact and superficial pressure, and not much increased by deep pressure. Opium had been given in various forms and bromides, and, as need scarcely be said, all the precautions against septic infection of the perineal wound had been taken. In deciding to recommend the employment of the douche I concluded that the abdominal respiratory movement excluded peritonitis, while the character of the pyrexia was not that of puerperal fever or septicaemia; the local tenderness again, in the left iliac fossa, was not accompanied by any tumefaction suggestive of pelvic cellulitis or ovaritis, and, as has been already said, it was remarkably superficial. It seemed, therefore, that the pyrexia and the sleeplessness were what we had to deal with, and that if they could be overcome there was every reason to expect that the patient would do well; while it was obvious, on the other hand, that persistence of a temperature of 104° , with entire absence of sleep, was attended with grave peril. It was agreed that she should be sponged all over with tepid vinegar and water, and that to the head, chest, and back the cold douche should be applied in the way described in the previous case. These measures were carried out; and, as I was informed by Mr. Ord, the patient speedily fell into a calm sleep, the pain in the iliac fossa subsided, and the temperature fell. There was no further complication, and satisfactory convalescence followed.

ON TWO CASES OF REMOVAL OF IMMENSE FATTY TUMOURS BY ABDOMINAL SECTION.¹

By JOHN HOMANS, M.D., Boston, U.S.A.

I AM not acquainted with any reports of the removal of fatty tumours from within the abdominal cavity approaching in size those to be described in this paper. As I have met with these two, probably other operators of greater experience have met with more. Mr. Cooper Forster showed at the Pathological Society of London on March 14th, 1868, a fatty tumour, weighing 55 lb., removed after death from the abdomen of a woman. This case, and an unreported one mentioned to me by Professor Calvin Ellis, of Harvard University, are the only ones I have heard of. Dr. Ellis thought that the one he removed after death might possibly have been successfully removed during life. In the first of my two cases I made an antiseptic exploratory incision, and thought I could not successfully remove the tumour (and in this opinion I was right). The patient recovered so easily and rapidly from the operation, however, that I felt emboldened to make another and more thorough attempt, which, I regret to say, resulted fatally.

CASE 1. *Immense Myxo-lipomatous Tumour within the Abdomen.*—Francis C. G., a porter, thirty-nine years old, a native of Germany, came to Boston at the age of ten, and has lived here since. In July, 1861, he enlisted in the 20th Massachusetts Infantry, and served gallantly through the war. He lost his left forearm at Fredericksburg in the assault under Burnside, but was never otherwise sick or injured. After he returned from the war he worked as janitor and porter in a large office building, and carried heavy ash barrels weighing 150 lb. apiece down five flight of stairs by swinging the barrel on his back, and holding it by the handle with his right hand over his shoulder. He also carried hods of coal upstairs, and had the care of twenty-five fires during each winter. He gave up his place in 1879, and was afterwards unable to find work that he could do. During 1879 and 1880 he did not feel strong, and was troubled with palpitation, heartburn, loss of strength, and more or less loss of mental power. After standing a few minutes he would feel numbness in both thighs, as though they were "asleep;" this sensation induced him to sit down, but if he struggled against this desire and walked about the feeling disappeared. Until the summer of 1880 he had had no dyspnoea; he had never had syphilis. He had been in the habit of drinking two glasses of lager beer daily for about eight years, and had smoked tobacco somewhat. He had not slept very well during the year 1880. Two years and a half ago—that is, in 1878—he first noticed that his abdomen was becoming swollen, but he thought it was a natural increase of size, and that he was simply growing stout. In the early part of 1880 he began to lose flesh and strength, and became gradually more and more emaciated. He entered the Massachusetts General Hospital in Feb. 1881, and remained about three weeks. No definite diagnosis was made. The urine was somewhat, but not remarkably, diminished in amount. I saw him in July, 1881. The tumour had grown considerably larger than it was when he left the hospital. His abdominal girth at the umbilical level was $42\frac{1}{2}$ in., and from the ensiform cartilage to the pubes the distance was 18 in.; from one anterior spinous process of the ileum to the other was $22\frac{1}{2}$ in. The different organs of the body were essentially healthy

¹Read before the Boston Society for Medical Improvement, Dec. 11th, 1882.

so far as could be ascertained. A careful examination of the abdomen was made many times. There was a uniform bulging in every direction, and the distended walls projected somewhat over the thighs. The tumour felt so fluctuating in parts that it was punctured several times, but only a little bloody fluid was obtained. This was examined by Dr. Gannett, and the following is his report:—

"6 Park-square, Aug. 3rd, 1881.

"Dear Dr. Homans—The fluid, of a dark-brown color, very opaque, gives slight precipitate with nitric acid. On standing, abundant brown sediment, clear supernatant fluid. Microscopically, sediment made up of very numerous fresh red blood corpuscles and a large amount of finely granular material, wholly soluble in acetic acid. No cells of any sort were found, and nothing to indicate the origin of the fluid. From its solubility in acetic acid, the granular matter is undoubtedly albuminoid. I am unable to make any diagnosis from the few characteristics found in the specimen.

(Signed) "W. W. GANNETT."

My diagnosis was a tumour of unknown character in the abdomen, without much adhesion, apparently a large myxoma, or a lipoma, or a colloid growth. After many examinations and consultations a room was hired in the Carney Hospital, and the patient's board was paid by a subscription of his comrades and friends in the 20th Massachusetts regiment and elsewhere, and on Oct. 30th, 1881, I made an incision under the spray about fifteen inches long from above the umbilicus to the pubes. The tumour on being exposed looked like an ordinary fatty tumour; it was smooth and lobulated. It was slightly adherent to the liver, and was covered with a delicate, smooth, envelope-looking like peritoneum. It seemed to be about two feet long and a foot thick. The incision enabled me to pull the tumour out of the abdomen considerably, and it was found that the envelope covering it ran down to the spinal column, and was then reflected upon the parietes. No intestines were seen. At the lower part there were no adhesions to the bladder, but the tumour seemed to have a central attachment extending from the neighborhood of the coeliac axis downwards and sideways, on both sides of the vertebral column covering a space considerably larger than the palm of the hand. My explorations were made for the most part on the left side of the abdominal cavity, and after ascertaining with some indefiniteness the attachments of the growths my courage failed, and I thought it wise to replace the tumour and close the incision. I doubted whether I could control the hæmorrhage accompanying its removal, and I feared that some of the abdominal organs, particularly the intestines or a kidney, might be included in the tumour. It was with the greatest difficulty that the tumour was pushed under the abdominal parietes and behind the pubes, and held there by three strong men while numerous stitches brought the edges of the incision together. Finally, fifty-six stitches held the wound firmly, and the tumour remained within the abdomen. The patient recovered completely from this exploratory operation and showed great strength of constitution. His convalescence was accompanied by much pain and diarrhoea, but the wound healed rapidly and solidly. He returned home at the end of four weeks and gained strength rapidly. He gradually increased his exercise until he began occasionally to come to Boston, from Cambridgeport, where he lived, a distance of two miles, in the horse-cars. The weight of the tumour annoyed and distressed him, but he found it much easier to carry after his wife had made a stout

supporting sling, held up by straps over his shoulders. As time went on he became anxious to be relieved of his burden, in order to be able to work and earn his living. After due consideration and reflection, we decided to remove the tumour. Mr. G— said, "My life will not last long with this increasing burden, and if there is such a thing as removing the tumour, I wish you would do it. I am not afraid to die, doctor, and it's neck or nothing this time." From the knowledge obtained at the exploratory operation, and from the endurance the patient had shown, I began to think that perhaps I could safely remove the tumour and that its attachments might not be inseparable. Whether our decision were wise or foolish, the operation was decided upon.

On Feb. 5th, 1882, I made another attempt, assisted by Drs. A. T. Cabot, E. G. Cutler, M. H. Richardson, F. C. Watson, Mixter, Russell Sturgis, and Messrs. Sparhawk, Holden, Godding, and several others. Two tumours, weighing with their pails 57 lb., were removed. An incision about seventeen inches long was made to the left of the scar of the exploratory incision, and a transverse one about four inches long was made on the left side at right angles with the longitudinal one. The large lobulated fatty tumours had no anterior adhesions except to the cicatrix of the former incision, but they were adherent to the ascending colon which crossed them transversely. The tumours seemed to have originated behind the peritoneum on the right side, and had pushed all the bowels towards the left side, except the ascending colon. If these tumours had been situated outside the skeleton—i.e., outside any of the great cavities of the body—they could have been safely enucleated; they were covered with a capsule, and from this they could be peeled out. The capsule was more or less torn and ruptured, and the tumour raised with great difficulty, owing to its weight. The ascending colon was separated from the tumour and rolled off, after dividing and tying most of its mesentery. The vascular attachments were clamped and tied and burnt off from time to time as was necessary, and the tumour was lifted out of the abdomen. When this tumour was removed another one, apparently purely myxomatous, was exposed to view. After some hesitation this was removed also. It occupied the right lumbar and hypochondriac regions, and had pressed the liver upwards and to the left into the epigastrium. The shining capsule (peritoneum) of this tumour was tough and strong; some of it was removed with the growth, and some of it was peeled off and left behind. All bleeding points were secured, and the abdomen thoroughly cleansed. Another tumour was now seen, about ten inches long, and lying on the abdominal aorta, and pulsating with it. This was not disturbed. Everything looked as favorable as one could expect after so severe an operation. There had not been much blood lost; the pulse was 85, and feeble, but not extremely so. Two atomizers had played a spray of a 5 per cent. solution of carbolic acid upon the abdomen, and the operation had been thoroughly antiseptic. The intestine which had been pushed off the tumour, or rather from under which the tumour had been withdrawn, was largely deprived of its mesentery, and might not be well nourished, but with this exception affairs looked as promising as after a severe successful ovariectomy. The patient was placed in bed with his feet elevated and warmed with hot bottles. The operation lasted an hour and a half. During the afternoon, the operation having been finished at half-past twelve, he seemed to be doing well, and at half-past five asked for a drink of water. His wife brought it to him, when he said, "I think I am going," and

died. I append an account of the autopsy, and a description of the tumours by Dr. W. W. Gannett, who has kindly written them out for me.

Autopsy, forty-six hours after death.—Body considerably emaciated. Anterior abdominal walls flaccid, flabby, and thrown into numerous folds. A linear incision from about ten centimetres below the xiphoid cartilage to the pubes. A short cross incision at the umbilicus stitched together. In the abdominal cavity about fifty cubic centimetres of bloody fluid. The ascending colon hung free like a rope in the abdominal cavity, having no mesocolon, its usual point of attachment showing a reddened ragged edge. The whole posterior right wall of the abdominal cavity had a ragged irregular surface; from this the tumours had been removed. On the left side posteriorly to the peritoneum was a flattened round mass the size of a man's head, showing the same fatty mucous structure as those previously removed. Another mass about three times the size of the fist, and of the same structure as the preceding, lay over the inferior vena cava, and was adherent to it and to the duodenum. The right kidney was of the usual size and density, and of a pale color; on section, it showed a yellowish opacity of the cortex and a moderate degree of fatty degeneration. The left kidney was apparently normal. The other organs presented no unusual appearance. The head was not examined. The tumours were retro-peritoneal.

Dr. Gannett's Report of the Tumours removed on the 5th of February, 1882.—1. A flattened globular mass, measuring $38 \times 33 \times 12$ cm., and weighing 25½ lb. The outer surface showed a shreddy, glistening, white surface, from which numerous thin connective-tissue layers could be picked off. One portion was hanging loose, and a mass of connective-tissue, about 20×20 cm., and about 3 mm. thick, formed a tough membrane, the under surface of which, corresponding to the tumour, was ragged, the upper smooth and shining. The density of the mass was about that of firm wine jelly. On section the cut surface showed a very delicate pale connective-tissue meshwork, enclosing large spaces which were filled with a thick, syrupy, pale-yellow, almost transparent fluid, coagulating on the addition of acetic acid. 2. The second tumour: A coarsely irregular mass of pale-yellow color, and somewhat doughy consistence, measuring $37 \times 31 \times 16$ cm., and weighing, with the mass next to be described, 24 lb. On section the surface showed a twofold appearance. A homogeneous, opaque, yellow tissue, resembling fat tissue. Imbedded in this were greyish, homogeneous, translucent, soft, gelatinous nodules, varying in size from that of a filbert to that of the fist. On scraping the cut surface of the latter, a thick, homogeneous, nearly transparent fluid was obtained. 3. A mass similar in character to the last (2), which was torn away from it during the operation of removal; it measured $34 \times 17 \times 15$ cm., and weighed, with 2, 24 lb., and presented the same appearance. 4. Several smaller nodules, of a flattened, globular form, varying in size from a walnut to a large peach. On section they presented a somewhat translucent yellow, as if made up of a fat tissue rich in connective tissue. Microscopic examination of gelatinous portions of the above-described tumours, frozen and sections made, showed a stroma made up of very delicate connective-tissue fibres running in various directions, and enclosing spaces in which was a clear refractive substance, giving a marked mucin reaction; the remaining portion showed the structure of fat tissue.

CASE 2.—On August 8th, 1881, I saw Mrs. V—, aged sixty. I learned that she had always been well and strong, and had had several children.

Her father died at the age of sixty-six of cancer of the rectum, and a brother had died of cancer of the liver. On examination I found a large fluctuating abdominal tumour, without impulse, and containing solid masses. During the previous six months it had grown rapidly. The umbilical girth was 41 in. I aspirated the tumour in many places where fluctuation seemed most distinct, but got no fluid, not even blood. The abdominal parietes in the pubic region were oedematous, and the lower extremities had been so. Her complexion was somewhat sallow, but had formerly been ruddy. The next day I aspirated with a good-sized needle, but could get no fluid. The result of my tapping and the family history decided me not to recommend an operation. The patient was bright, sagacious, and sensible. I suggested an exploratory incision at some future time, but rather discouraged any interference, though I promised to attend her if sent for.

Accordingly, in March, 1882, at her request, I operated at her home. Her umbilical girth was now 53 in., the oedema of the abdominal walls was greater, and her lower limbs were much swollen. The tumour was exposed by a long incision, and appeared to be an immense lipoma. It had originated on the right side behind the peritoneum, and as it grew had pushed the bowels before it, as in the previous case. It was adherent to the peritoneum, from which it was more or less neatly enucleated with free hæmorrhage at times. The ascending colon crossed over it as in the previous case, and the cæcum, colon, and the appendix cæci were almost incorporated in the mass. The tumour dipped deeply into the pelvis, and almost filled it, and was at length, after considerable hæmorrhage and much shock, removed. The operation lasted about an hour, and the tumour weighed 35 lb. She never rallied, and died soon after being placed in bed. Dr. Gannett reported that the tumour was a pure lipoma.

It seems to me proper and important to put these cases on record. The propriety of operating is, of course, open to discussion. It is very hard, however, to stand idly by and see persons sink slowly under mechanical pressure, which we cannot remove by tapping.

In Mr. Cooper Forster's case before referred to, both Dr. Wilks and Dr. Hicks believed the tumour to be a collection of fluid, the percussion wave being perfect. The ascending colon lay in front of the tumour, and there was a little fluid between it and the walls of the abdomen. It was adherent to the diaphragm, and when removed weighed 55 lb. It had no distinct pedicle, so it was a question how it originated. It will be seen that these two tumours and the one exhibited by Mr. Cooper Forster were crossed by the ascending colon, and it would seem impossible to remove such tumours without disturbing the vascular connections to such a degree as to cause gangrene of the bowel. In another case I should be rather inclined to make an artificial anus in the cæcal region, or resect the intestine that had been deprived of its mesentery. The latter procedure would be extremely difficult in the case of the ascending colon, which is much bound down in the right lumbar region. At my request Dr. Gannett has carefully searched all the German, French, and English periodicals and publications, but has not found a single case of retro peritoneal fatty tumour. Fatty tumours of the omentum and mesentery are not very unfrequently described. Leopold² and Kroner³ have collected seventy-six cases of extirpation of the kidney, but none for fatty or mucous

tumours. One of these was a retro-peritoneal fibroma removed by Billroth,⁴ and Bruntzel, Breslau, reports⁵ an extirpation of the left kidney for a fibroma of the renal capsule, weighing 37½ lb., and followed by recovery with a fecal fistula. The patient was an unmarried woman, thirty-three years old. The tumour was of eight years' growth and painless. Bruntzel's treatment of the wounded and torn peritoneum is interesting and instructive. In removing the tumour, which was retro-peritoneal, the peritoneal sac was twice incised. The two ragged posterior peritoneal surfaces were brought into contact, and the anterior edges were stitched to the anterior abdominal wall in the lower part of the incision, thus providing for drainage from the space between the two folds. The paper is a highly interesting one, and is made clearer by two woodcuts. The tumour was a fibroma with a considerable amount of fatty tissue in it.

Boston, U.S.A.

THROMBOSIS OF THE RIGHT SIDE OF THE HEART FROM INTENSE MENTAL EXCITEMENT.

By KEITH N. MACDONALD M.D., F.R.C.P. Edin. etc.

THE following case presents some points of interest both from a pathological and medico-legal point of view, inasmuch as it tends to show the powerful influence of mental emotion as a factor in the production of sudden death; and one which ought not to be lost sight of in reckoning the causes of the existence of fibrinous coagula in the heart, independent of the morbid lesions and states of the blood which are usually credited with producing that condition. The case under consideration was brought to my notice through a judicial investigation which was instituted by the procurator fiscal of this county (Fife) in order to ascertain the cause of death of a woman who was found dead in the street under peculiar circumstances. On the night of Nov. 14th, 1882, I was called by the police, shortly before midnight, to see a woman, then unknown, who was found in an unconscious state in the street, and who was taken to the police office, together with a young man, a stranger to the town, who was seen to assist her when she fell. On my arrival, a few minutes after being called, I found that she was dead, and the young man was detained overnight for further inquiry. Next morning, Dr. Douglas and myself were instructed to make a post-mortem examination of the body, and were furnished with the following history of the case. The investigations of the police brought to light that she was a very respectable, steady, and hard-working woman, aged thirty-four, wife of a factory tenter, and mother of two children; that about eleven o'clock on the previous night, in consequence of her husband having come home the worse for drink, she flew into a violent passion, an altercation ensued, and she left the house in a state of great excitement, tinged with jealousy, and was proceeding to a friend's residence at some distance, where she had on several occasions taken refuge before, to spend the night, when the fatal illness attacked her. From the husband we further learnt that, with the exception of occasional headaches, she had previously been in the enjoyment of robust health, and, as far as we could make out, her family history was good.

Autopsy, eleven hours after death.—The body,

⁴ Wiener Med. Wochenschrift, 1880, No. 28, reported by Buselmann.

⁵ In the Berliner Klin. Wochenschrift, Dec. 4th, 1882, No. 49.

which was that of a comparatively young, good-looking woman, well nourished, had no marks of injury upon it. The face was placid and tranquil, eyes closed, lips apart, nostrils depressed, hair long and fair; fingers flexed and elbows slightly bent. There were livid patches of discoloration around the ears, extending on to the cheeks, and hypostatic congestion existed over the posterior aspect of the body. Rigor mortis well marked. Cranium: On removing the skull-cap the dura mater was found adherent along the temporal and parietal regions, and the longitudinal sinus was filled with dark fluid blood. The vessels of the pia mater appeared dark and prominent, and it and the arachnoid could be readily stripped from the surface of the brain matter. The basal arteries and their branches, so far as they could be traced, were normal. On slicing the hemispheres from above downwards, the convolutions of the gray matter appeared more congested than the white substance, which also presented numerous bloody points. The right lateral ventricle contained two drachms of serous fluid, the left being almost empty, and the choroid plexuses on either side formed fringes of injected blood-vessels. The corpus striatum, optic thalamus, medulla oblongata, and cerebellum were also more or less congested, and the fourth ventricle was empty. No other change worth nothing. Thorax: Heart walls normal; pericardium empty; right ventricle filled with dark coagulated blood entangled amongst the columnæ carneæ and chordæ tendinæ, extending into the pulmonary artery, right auricle, and inferior vena cava, neither decolorized nor laminated, but slightly adherent to the trabeculæ of the right ventricle. Left auricle and ventricle nearly empty. The mitral and aortic valves presented a few minute patches of atheromatous degeneration, otherwise healthy. Section of the lungs displayed intense congestion and some œdema with fatty mucus tinged with blood, which at first appeared like thin pus which was not verified on microscopic examination.

At this stage of our examination we were informed by the public prosecutor, after full investigation into the general facts of the case, that if we were satisfied death was due to natural causes, he was unwilling to inflict further pain upon the relatives by continuing our dissection, to which we assented, and reported accordingly that the cause of death was thrombosis of the heart and pulmonary embolus.

Remarks.—The only weak part in the above case is the absence of details regarding the state of the kidneys, and other abdominal organs, but as the history of the case pointed so clearly to a robust condition of health prior to the date of her death, and it having been brought out in evidence that she was a person of a very violent disposition, I can only end as I began, by asserting that, in my opinion, mental emotion was the immediate cause of the sad catastrophe.

Cupar Fife.

ABSTRACT OF THE REPORT ON THE RELATION OF MICRO-ORGANISMS TO TUBERCULOSIS.

Presented to the Association for the Advancement of Medicine by Research on Feb. 1st, 1883.

By W. WATSON CHEYNE, M.B. F.R.C.S.,
Assistant-Surgeon to King's College Hospital, etc.

A VISIT was paid to Professor Toussaint, of Toulouse, and to Dr. Koch, at Berlin, with a view of seeing their methods of experimentation, and the results which they had obtained. Various experi-

ments were seen, and a quantity of material was brought back to England for more detailed examination. The result of the visits, and a full account of the observations made, will be found in the complete Report, which will be published in the April number of the *Practitioner*.

It was thought advisable in the first instance to repeat some of the experiments which have led observers, more especially in this country to object to the view of the specific origin of tuberculosis, and to hold that in rodents, at least, any irritation might produce that disease. The present series of experiments were performed under the best hygienic conditions, with complete isolation of the animals from each other, and with thorough disinfection of the instruments employed. In six cases setons of various kinds were introduced both subcutaneously and into the anterior chamber of the eye; in ten, vaccine lymph both from the calf and from man was employed; in three pyæmic pus was injected (1) into the eye, (2) subcutaneously, and (3) into the abdominal cavity; and in six various materials (cork, tubercle hardened in alcohol, and worsted thread) were introduced into the abdominal cavity. None of these twenty-five animals became tuberculous. Some experiments are also cited in the report in which wounds in rodents have been stitched up with cotton thread, and others in which abscesses have been produced in various ways, but in none of these cases did tuberculosis ensue. In explanation of the former results, it is pointed out that at the time the early experiments on this subject were made the communicability of tubercle by mediate contagion was not recognized, and, as the precautions necessary for thorough disinfection of instruments, etc, had at that time not been made out, the channels for the introduction of specific micro-organisms were left unguarded.

Two tubes of serum containing micrococci were obtained from M. Toussaint, who holds that micrococci are the cause of the disease. Toussaint obtains the organisms by inoculation of flasks containing serum, or infusion of rabbit with the blood of tuberculous animals; and he has in some cases succeeded in producing tuberculosis by the injection of these cultivations into other animals. The material obtained from M. Toussaint was injected into three rabbits, two guinea-pigs, one cat, and one mouse, and of these seven animals six were under observation for a sufficient length of time for the development at least of local tuberculosis. In no instance did tuberculosis ensue. (In all the experiments detailed in this report inoculation was made into the anterior chamber of the eye, whenever this was practicable; syringes purified by heat were employed for the purpose.) Cultivations of these micrococci were also made, and injected into nine rabbits and three guinea-pigs. Of these four rabbits and three guinea-pigs were under observation for a considerable time without the development of tuberculosis in any case. The total result is that thirteen animals were inoculated with the micrococci with which Toussaint works, and obtained from Toussaint himself, and in no case did tuberculosis occur.

A number of tuberculous organs from animals experimented on by M. Toussaint were also obtained, some of the animals having become tuberculous after the injection of the micrococcal fluid. Careful examination of these organs has shown the presence, often in large numbers, of the tubercle bacillus described by Koch, but no micrococci have been found. The conclusion arrived at is that the micrococci described by Professor Toussaint are not the cause of tuberculosis. One of the possible explanations of the results which should not be left out of account is the following:—Pro-

fessor Toussaint trusts greatly to carbolic acid as a disinfecting agent for the purification of the instruments employed in inoculation. This antiseptic, though effectual for the destruction of the ordinary forms of micro-organisms, as evidenced by the satisfactory results obtained from its use in aseptic surgery, has been shown to be ineffectual against the spores of bacilli, unless it acts for a long time. The bacillus of tubercle apparently produces spores, and there is no reason to suppose that these are less resistant than those of bacillus anthracis, and other bacilli. An experiment is given which shows that a saturated watery solution of carbolic acid, even though it acts as long as fifteen minutes, is not sufficient to arrest the development of the tubercle bacilli. Therefore, to wash a syringe with carbolic acid is not such a certain means of disinfection in this particular instance as was formerly supposed. Experiments were also made with cultivations of tubercle bacilli obtained from Dr. Koch. Twelve animals were inoculated with these organisms, chiefly into the anterior chamber of the eye, and all of them became tuberculous, and that more rapidly than after inoculation of tuberculous material. The tubercles produced in these cases were infective, and caused tuberculosis in other animals. On examination of tuberculous material, Koch's tubercle bacilli are always found, though in varying numbers. They are most numerous in bovine tuberculosis, and least numerous in human tuberculosis. About eighty organs of tuberculous animals and thirty-six cases of human tuberculosis were examined, and in all of these, without exception, tubercle bacilli were found. The inoculation of these bacilli is more certain and more rapid in its effect than the inoculation of tuberculous material from any source; and this seems only explicable on the supposition that in the cultivation of these bacilli the virus of the disease is present in a more or less pure state, and in large amount. Various facts are pointed out leading to the conclusion that in these bacilli we have the virus of the acute tuberculosis caused in the lower animals by the inoculation of tuberculous material.

In applying the facts obtained from experiments on animals to the pathology of tuberculous diseases in man, it is pointed out that all that has as yet been absolutely proved is that a variety of materials in man, which we class together as tuberculous, produce acute tuberculosis, when inoculated into rabbits, guinea-pigs, and other animals, and that this result is due only to the tubercle bacilli present in the materials inoculated. It therefore remains for inquiry, what relation these bacilli bear to the morbid processes in man in which they are found.

Acute miliary tuberculosis in man resembles in every respect, in histological structure, in tendencies, and in the presence of bacilli, the disease produced in the lower animals by the inoculation of tuberculous material; and there can be little doubt that the cause of both diseases is the same—viz., the tubercle bacillus. It is, however, much more difficult to understand the relation of these organisms to localized tuberculous processes in man (phthisis, scrofulous diseases of glands, joints, etc.). Phthisis is alone considered in the present report, and, with a view of making clear the conception which the author has formed as to the relation of bacilli to this disease, the following facts are brought forward, which he has observed as to the mode of distribution of the organisms in the tissue, and their relation to its histological elements.

Two distinct structures have been described as tubercles in lungs of rodents—viz., nodules of lymphatic tissue in close proximity to the vessels

and bronchi, and nodules which are largely made up of epithelioid cells. If a case of commencing artificial tuberculosis is examined, it will be found that bacilli are only present in the latter nodules; indeed, it is rare even in the later stages to find them in the former, and in that case epithelioid cells will be found as well. The bacillus being the cause of this disease, the nodules containing epithelioid cells are alone tubercles. Further, on careful investigation of these nodules, it will be found that bacilli are only present in the epithelioid cells themselves. In making this statement only young tubercles and those in which the bacilli are present in moderate numbers are referred to. When there are enormous masses of bacilli, or where there has been confluence of tubercles forming a largish tuberculous deposit, some bacilli may be found in the outer part of the tubercle, but the great majority of them occupy the epithelioid tissue. When the bacilli are few in number, one need only look for them in the epithelioid cells. Around the epithelioid cells the tissue becomes inflamed, and converted more or less completely into granulation tissue. As the tubercle becomes older the epithelioid cells at the centre undergo caseous degeneration, and in this case the bacilli are present in the caseous mass; but are often best seen at its margin, where epithelioid cells still exist, and they may also be found penetrating into the inflammatory tissue. The giant cells of tubercle can be distinctly traced as originating from epithelioid cells, especially from epithelioid cells containing bacilli. As to the origin of these epithelioid cells in the lung, the great majority are derived from the alveolar epithelium. The bacilli escape from the blood-vessels or lymphatics and pass into the alveolar epithelium, where they grow and cause multiplication of the epithelial cells until the alveolus becomes completely filled with them. In some instances, however, those cells are probably derived from the endothelium of blood and lymphatic vessels. In the case of the liver, the author thinks they are frequently developed from liver cells, for bacilli have been found in liver cells at the margin of commencing tubercles, and gradations in size and form can be traced between those liver cells and the epithelioid cells in the centre of the tubercle. The accumulation of the epithelium in the centre of the nodules leads to obliteration of the vessels around and to fusion of neighboring nodules. With regard to phthisis, the two extremes, the rapid phthisis or caseous pneumonia, and the chronic or fibroid phthisis are considered. In the rapid phthisis the alveoli are distended with caseous material, or in parts where the process is less advanced with epithelioid cells. Surrounding these, the trabeculae are thickened, and converted into granulation tissue. Here the bacilli are found in moderate or considerable numbers in the caseous material and epithelioid cells which fill the alveoli. By-and-bye the walls of adjacent alveoli disappear, and thus irregular cavities are formed containing caseous material surrounded by epithelioid cells and inflammatory tissue. In this case the bacilli are most numerous, and sometimes in enormous masses at the free margin of the cheesy material, and they are also present, though not as a rule so numerous, in the epithelioid cells at the line of junction of the caseous mass with the surrounding tissue. In fibroid phthisis the bacilli are, as a rule, extremely few; but here and there if a cavity exists, or in the centre of a caseous mass, one may find them in considerable numbers. They may, though very rarely, be also found in the giant cells, which are generally pretty numerous among the fibrous tissue. As a rule, however, the bacilli are extremely few, but nevertheless, if a sufficient

number of sections be carefully examined, a few will be found here and there at the margin of or in the caseous masses.

The foregoing facts seem to indicate that when the tubercle bacilli reach the alveolus of a lung which is in a suitable condition for their growth, they develop in the epithelial cells lining the alveolus. This alveolus becomes filled with cells, neighboring alveoli become affected, and the same process goes on in them. The further result will depend on the number and rapidity of growth of the bacilli, and on whether the patient is a good soil for their development. If they develop well we have caseous pneumonia; if they grow slowly and with difficulty we have fibroid phthisis. In the former case the alveoli become early distended with epithelioid cells, inflammation of the walls of the alveoli ensues, the epithelioid cells soon undergo caseous degeneration, and the presence of the masses leads to atrophy or sloughing of the walls of the alveoli. Infection of neighboring parts of the lungs occurs by continuity, and also by partial coughing up and re-inhalation of the bacilli into other parts of the lung. In this rapid phthisis fibrous formation around the alveoli only takes place imperfectly, and the lung rapidly breaks down. In the case of fibroid phthisis the bacilli are few, and grow only with difficulty. Thus fibrous formation occurs extensively, and giant cells are entangled in the fibrous tissue. In parts, however, the process may be more rapid, and there cheesy masses are formed, which may lead to breaking down of the lungs and the formation of cavities.

In the report it is pointed out that on this view we have one explanation of the rarity of acute tuberculosis in connection with phthisis, and of the presence of bacilli in sputum, even before physical signs are marked, while it is shown that this view is directly corroborated by the results obtained by Tappeiner in his inhalation experiments. Against the statement that phthisis is due to the tubercle bacilli might be urged the fact that the bacilli found in the lung after death are often very few in number. Among other facts brought forward with regard to this question, it is stated that extensive tuberculous processes may be found in animals, containing only few bacilli, and that in cases where bacilli alone were inoculated, and where it is certain that the bacillus was the only agent at work. With regard to the production of phthisis by the inhalation of dust of various kinds, it is pointed out that the foreign particles inhaled probably only prepare the lung for the reception of the bacilli; for in these cases also bacilli are found. It has often been urged that the milk of tuberculous cows is infective. This may be the case when the mammary glands become tuberculous, and the mode in which the bacilli might get into the milk was well illustrated by the appearances found in a tuberculous kidney. There not only were bacilli present in the tuberculous mass, but they were also found in large numbers in the epithelium of the kidney tubules and in the interior of these tubules, both in the vicinity of the mass and at some distance from it. The author has not yet investigated the subject of tuberculosis of the kidney, but from what he has seen he thinks it probable that the epithelium of the tubules is the favorite seat of the bacilli in the kidney, just as the alveolar epithelium is in the lung. In that case bacilli would be present in the urine, not merely when there were marked tuberculous masses in the kidney, but also where the disease was but slightly advanced. From analogy it is probable that the same is the case in the mammary glands, and bacilli might be present in the milk, even though the disease of

the gland was not sufficiently advanced to be noticeable.

The staining solution employed was the Weigert-Ehrlich solution. The formula is: of a filtered saturated watery solution of anilin one hundred parts, of a saturated alcoholic solution of the basic anilin dye (methyl violet, gentian violet, fuchsin, etc.) eleven parts. Mix and filter. Rapid staining is obtained by warming the solution. The specimens are then decolorized by immersion in nitric acid (one part to two of water), and stained in a suitable contrast color. Very delicate sections are apt to be injured by immersion in the nitric acid. In this case, after staining them in the Weigert-Ehrlich fuchsin solution, they may be washed in distilled water, immersed in alcohol for a moment, and then placed in the following contrast stain for one to two hours: distilled water 100 ccm., saturated alcoholic solution of methylene blue 20 ccm., and formic acid 10 min. Whenever it is possible, however, Ehrlich's original method is recommended, as being most rapid, most simple, and most satisfactory. By this method of staining, tubercle bacilli and leprosy bacilli remain red. Psorospermia and the outer coat of some parasites also retain the red color. Lichtheim has further stated that a micrococcus is frequently found in the feces, which reacts in a similar manner to the tubercle bacillus.

ON ENDEMIC HÆMOPTYSIS.¹

By DR. MANSON,

of Amoy, China.

THE work of Bilharz, Griesinger, Cobbold, Dr. J. Harley, Sonsino, and others, has made us familiar with the parasitic affection of the urinary organs known as endemic hæmaturia. I propose to notice a disease of the lungs almost the exact counterpart of this of the urinary organs, and, following the example in the nomenclature of endemic hæmaturia, I will call this new disease "endemic hæmoptysis."

The parallel that obtains between these two diseases is very remarkable. Endemic hæmaturia and endemic hæmoptysis are both of them caused by parasites; in both diseases the parasite is a species of distom. Both affections are characterized by an intermitting or remitting discharge of blood, and in each the ova of the parasites are to be found in this discharge. Both have a limited and probably well-defined geographical distribution, and both tend perhaps to shorten life either by profuse hæmorrhage or the gradual sapping of health consequent on long-continued and frequently repeated small bleedings.

My acquaintance with endemic hæmoptysis dates from the middle of April, 1880. At that time I was practicing in Amoy. For a purpose altogether unconnected with the subject of these remarks, I had for some time been in the habit of examining with the microscope the blood brought up from the lungs in all the cases of hæmoptysis I met with in native practice. On one occasion I was consulted by a Chinaman about a trifling skin disease. Whilst he was describing to me his symptoms he was seized with a fit of coughing, and brought up a small quantity of blood-tinged sputum. I transferred a small portion of the sputum to a glass slide and examined it with the microscope. I found plenty of blood and mucous corpuscles, epithelium, and so forth, and in addition to these I observed certain large bodies such

as I had never met with before, and which I suspected, from their appearance, were the ova of a parasite. These bodies were in great abundance, some three or four of them in nearly every field. They were oval, dark reddish-brown, double outlined, operculated at the broader end, and contained one or more paler spheres suspended in a granular matrix. There was some diversity both in size and shape. Some were more spherical; others, again, more elongated. On an average they measured 1-300th in. by 1-500th in. These bodies were undoubtedly ova; but, thinking they might have been accidentally introduced into the man's mouth in his food, or possibly that there might be a parent worm about his mouth or throat, I examined his oral cavity very carefully. I found no trace of food or parasite, and when, on requesting him to cough again and expectorate, I found that he produced a second pellet of bloody sputum containing similar ova, I concluded that a parasite must reside somewhere below the vocal cords, probably in the lungs, and that I had stumbled on a new disease.

The man told me he was a native of Foochow, was thirty-five years of age, and was a secretary in a mandarin's office. He had been in Amoy about a year only. When twenty-one years old he went to Formosa, where he resided, with the exception of two or three visits to the mainland, for nearly ten years. It was during his residence in Formosa that his blood-spitting commenced—about a year after his arrival on the island. On his first attack he spat from half an ounce to an ounce of blood for nineteen days in succession. He emaciated slightly, but had very little cough. About six months later hæmoptysis returned—less profuse than on the former attack, but, as on that occasion, the sputum at the outset was pure blood. This second attack lasted for a few days only, but ever since he suffered from periodical attacks of hæmoptysis of two or three days' duration, and coming on every second or third month. He never had very much cough, nor had the hæmoptysis ever been very profuse, the blood after the first monthful or two always being mixed with mucus. Once during two years he had no attack whatever. His general health was satisfactory. A careful physical examination failed to detect anything amiss with heart or lungs that could account for the hæmoptysis. His family history was fairly good; his mother, he said, died of some disease of which cough was a symptom, but his father had never any sign of chest disease, and his four brothers and sisters were alive and well.

Two days after the first visit this man called on me again, and, as on the first occasion, brought up by coughing abundance of ova-laden sputum. Although he promised to see me again he did not return, and for a time my attempts to investigate a new and interesting disease were balked.

This man's case brought to my recollection that of a Portuguese, who had been my patient, suffering from aortic aneurism during November and December, 1878. This man, like my Chinese patient, had long resided in Formosa; indeed, he was only a visitor to Amoy when he came under my notice. He had been in bad health for some time, and a cold he caught so aggravated the dyspnoea he habitually suffered from that he was obliged to come to hospital. Under iodide of potassium and rest his urgent symptoms subsided, and he got well enough to return to Formosa about the end of the year. In the following June he died from rupture of the aneurism into the pericardium. Dr. Ringer, under whose care he had come, knowing I took an interest in the case, kindly sent me particulars of the post-mortem examination, and mentioned in his letter that on

¹ Read at the Medical Society of London, March 19th, 1883.

making a section of the lungs he encountered a parasite of some sort lying on the surface of his incision. Impressed with the great probability that a parasite of the same species that Dr. Ringer found in the lung of the Portuguese resided in the lungs of the Chinaman, and was the parent of the ova I found in such abundance in the sputa, I wrote to Dr. Ringer requesting him to send me the parasite, and in the sediment of the little bottle, in which it lay in spirits of wine, I had no difficulty in finding many ova corresponding exactly in size, shape, color, and contents with those I had found in the Chinaman's sputa. This parasite from the lungs of the Portuguese was of the same species as that producing the ova in my Chinese patient.

As far as I know this is the only specimen of this parasite that has been found; it is a distom. The spirit specimen, which had probably shrunk somewhat from its original size, measured half an inch in length by one-sixth of an inch in breadth by about one-third of an inch in thickness. It was quadrangular in shape, with the angles rounded off, of a bluish-grey color, and leathery consistence. I sent it to Dr. Cobbold, who pronounced it to be a new species, and named it, after the discover, *Distoma Ringeri*.

The gist of these observations was published in the China Customs Medical Reports for the half year ended Sept. 30th, 1880. In *THE LANCET* of the same year I read an abstract of a paper by Professor Baelz, of Tokio, Japan, which appeared to me to refer to the same subject. He described certain bodies found in the sputa of cases of hæmoptysis occurring in Japan. He considered these bodies to be a stage in the development of gregarinæ, and proposed to call the disease they were found in Gregarinosis pulmonum. I wrote the professor for specimens, and he very kindly sent me a small bottle from Japan containing characteristic sputum. Under the microscope I recognized the bodies he described, but they were in every respect identical with the ova associated with the solitary specimen of *Distoma Ringeri* I had examined, and with the bodies I found in such abundance in the sputa of my Chinese patient. I persisted in the examination of the sputa in every case of hæmoptysis turning up at the native hospital in Amoy. I examined over a hundred cases, but did not again encounter the ova in a single instance. My patients were all natives of Amoy or of the surrounding country. I suspected therefore that, like other distoms, the area of distribution of *Distoma Ringeri* was limited to certain districts, and that Amoy was not one of these. But I knew the parasite was to be found in Formosa. I therefore turned my attention to the natives of that island. On application to a friend residing in Formosa, I received two large bottles filled with sputa from two of his servants, which on examination were found to be crowded with distoma ova. In answer to a second appeal my friend sent his servants to Amoy to be under my immediate observation. The elder of these two men was a short, sturdily-built fellow thirty-one years of age. Until his visit to Amoy he had never been out of Formosa. His family, he said, was healthy. His father died of dropsy, aged fifty-eight, but his mother, three brothers, and four sisters were alive and well. His blood-spitting began about eleven years before I saw him. He was then working on the tea hills as an ordinary laborer. He observed that when he breathed hard during severe exertion cough came on, and with the cough expectoration of blood-tinged mucus. From that time he has been troubled with blood-spitting more or less constantly. It was always increased by violent exercise, and on one occasion, whilst rowing in a

boat, he suddenly brought up over a bowlful of pure blood. Occasionally coughing and spitting would stop for a few days, perhaps for a month, but then they would return and occur daily for a month or two. I auscultated this man's chest very carefully, but failed to detect any physical sign of disease. His throat was remarkably well developed, and altogether, though rather thin, he seemed to be in robust health.

The other servant was a tall, thin, rather delicate-looking young man, twenty-two years of age. Both his parents were dead: from what I could make out they died of some dropsical affection. He said he was quite strong till four years before the date of his visit to me; then, and without any obvious cause, he began to cough and spit blood, especially after exertion. During one year he continued to spit blood almost daily; about an ounce at a time. He then changed his employment to one in which less physical exertion was required. His hæmoptysis ceased and did not recur; but the cough continued, and now, almost daily, especially on rising in the morning, he has attacks of coughing ending in the expectoration of quantities of yellow-brown muddy-looking tenacious mucus. He complained of some pain about the left nipple, but on auscultating him I failed to detect anything amiss with the lungs.

While these two men lived in my house I examined their sputa daily. By getting them to cough I could always procure abundance of ova-laden sputum. So numerous were these ova, that I could procure thousands of them any time I chose to send for my patients. The fit of coughing which occurred on rising in the morning was always the most productive.

These men told me that blood-spitting was a disease to which Formosans and immigrants to the island were especially liable. In some districts it was very prevalent. I had only to request my friends there to send me some, and usually by return steamer I received three or four specimens coming from different blood-spitters.

The constant or repeated small bleedings these parasites induce cannot fail in certain cases to produce in time a state of intense anæmia, rendering the subjects of it very liable to attacks of dangerous forms of other disease. But the *Distoma Ringeri*, in consequence of the position it occupies, the lungs, and the liability of these organs to great strains and congestion on exertion or coughing, undoubtedly exposes its host to the additional danger of sudden and profuse hæmorrhage and the consequences, whatever these may be, of infarction of the lung tissue by effused or suddenly inspired blood. I am not in a position to assign to this parasite its exact share among the causes of grave disease, but I have no doubt that in time it will be found to operate prejudicially on the populations of the countries in which it is endemic in the directions I have indicated.

I need not enlarge on the symptoms and diagnosis of endemic hæmoptysis, but there is a point having very practical bearings—viz., the way in which the parasite and the disease it induces spread from one human host to another. By observing the specimens of ova under the microscope, it will be seen that they contain no trace of embryo. The ova passed in cases of endemic hæmaturia are occupied by a well-developed ciliated embryo, which escapes very soon from the shell.

The ova of other well-known distoms also develop a ciliated embryo. The development of the embryo of *Distoma Ringeri* was therefore the first point I had to attain before an intelligent idea could be got as to how the parasite spreads. My two patients supplied me with abundance of material for experiment.

It is evident that the sputum is the natural medium for the escape of the ova from the human host—just as in the case of Bilharzia the urine is—or, in the case of the intestinal and liver parasites, the intestinal discharges are. By following the destinies of sputum, therefore, I would perhaps be led to some knowledge of the development of the ova it contained. Seeing that the embryo was not at all developed, it was unlikely that the egg was immediately transferred to the body of the final, or, perhaps, of an intermediary host. As in other distoms, it was probable that there was a preliminary and ciliated stage in which the miniature parasite was free. When sputum is cast on the ground its destinies may be various. That which seemed to me the most conducive to the development of any ova it might contain was that it should be transferred by some agency, such as a shower of rain, to some pond, ditch, or well, where it might be incubated. I resolved to experiment in this direction. I placed specimens of distoma sputum in glasses, shook it up with filtered water, washed it daily for a week in fresh water, and then allowed the ova to settle quietly to the bottom of the vessel. In this way I fancied I imitated what must happen in nature. From day to day I examined ova thus treated with the microscope, and had the satisfaction of finding that a process of development led up to the formation of an embryo. At the end of from four to six weeks nearly every ovum contained active ciliated embryos closely resembling in appearance and habits those of Bilharzia and other distoms. Ova of the same age which I had not thus treated with water, but which had been kept in sputum as originally expectorated for comparison, exhibited no signs of development, and resembled in every respect freshly procured specimens.

When ova thus treated approach maturity, they present a very striking and interesting appearance. The embryo they contain is a delicate heart-shaped ciliated organism endowed with prodigious activity, incessantly occupied in attempts to rupture a collar-like membrane which surrounds its anterior extremity, and to force open the operculum of its shell. In time it accomplishes this, and by continued efforts, which can best be described as frantic, it squeezes its plastic body through the opening. Freedom obtained, it rushes through the water with great velocity, assuming varying forms. The cilia are in constant motion, and the whole appearance and behavior of the restless little animal convey the idea that it is searching for something. This something, I have little doubt, is its intermediary host. Its correspondence with the embryos of other and better-known distoms justifies the inference that its future history will bear a similar resemblance, and that the various stages of advancing development require its entrance into the body of some animal which will act the part of intermediary host. Now the necessity for the intervention of this intermediary host impresses on this parasite and the disease it produces their endemic character. Speaking roughly, parasitic diseases depending on parasites which do not require an intermediary host are pandemic. Again, if parasitic disease, whose parasite requires an intermediary host, does not occur in certain old countries, like China, we have a *prima facie* argument for believing that the intermediary host is not to be found there. From this I infer that the particular animal which acts the part of intermediary host to *Distoma Ringeri* is not to be found in China, but that it is a native of Formosa and Japan. Again, from the fact that the first step in development of the embryo takes place in fresh water, I infer that this intermediary host is a fresh-water animal. Therefore the inter-

mediary host of *Distoma Ringeri* must be searched for among the fresh-water animals common to Formosa and Japan, which are not natives of the neighboring mainland of China.

A glance at the map of Asia will show that Formosa and the great islands constituting the empire of Japan are by no means contiguous, whereas a very narrow belt of sea separates Formosa from the mainland of China. The distribution therefore of the intermediary host of *Distoma Ringeri* must depend on something other than mere latitude or temperature. There must be something in the soil or climate which Formosa and Japan have in common, and which is necessary to the well-being of the intermediary host, which China does not afford. I believe this element depends in some way on a volcanic soil. Unlike the mainland of China, both Formosa and Japan are actively volcanic. On this account, I believe, as research and our knowledge of this parasite extend, it will be found to prevail in other countries where a volcanic soil and certain ranges of temperature and moisture allow of the existence of the intermediary host. I have little doubt it exists in the Philippines and neighboring islands.

To return to my patients. The idea of curing them naturally occurred to me, and I made many attempts to dislodge their parasites. The accessibility of the bronchial tubes and tissues of the lungs generally to medicated vapors suggested inhalations of a parasiticide character. With a steam spray I atomized solutions and infusions of various substances, and caused my patients to inhale them. In this way quassia, koussou, santalin, turpentine, and sulphurous acid were applied to the lungs, inhalations being practised daily for a week in one case, and a fortnight in the other. But no mature parasite was brought up, only ova in abundance. However, three months after these inhalations the younger of my patients told me he was quite well; he had lost his cough, and no longer brought up rusty mucus. I irritated his lungs with fumes of burning sulphur, and thus caused him to cough violently, but the small quantity of bronchial mucus he brought up was quite destitute of ova. I believe he was cured. My other patient, I subsequently learned, was not benefited. Of course, the result of inhalations will depend in some measure on the position the parasite occupies in the lungs; if it is free in a bronchus we need not despair of dislodging it, but if it lies in the blood-vessels this may not prove so easy a matter.

From the facts I have adduced it is evident in what direction attempts at prevention should be made. It is only necessary to boil or filter drinking water, and never to eat uncooked vegetables or other uncooked food, to ensure immunity from endemic hæmoptysis in the countries where it prevails. London is a very cosmopolitan place, I doubt not, in the matter of disease, as in many other things, and just as we see natives of Japan and other countries in the streets, and meet Englishmen who have travelled or resided in foreign countries, so it is very likely you will meet in your hospitals or consulting rooms exotic imported diseases. I would recommend, therefore, in the event of your being consulted for chronic recurring hæmoptysis by a patient who has resided or travelled abroad, and in whose chest you can find no adequate reason for the blood-spitting, that you should place a little of his bloody or rusty sputum under the microscope.

—The authorities of the German Hospital at Dalston have secured the premises known as Graham House, directly opposite the hospital, to be used for convalescent purposes.

NOTE ON A PHASE OF INTOXICATION.

By WILLIAM S. SAVORY,

Surgeon to St. Bartholomew's Hospital.

In all that has been written on the subject of intoxication, one phase, and that perhaps the most common, of poisoning by alcohol has almost escaped description. Fits of drunkenness, in its various degrees, after a debauch on the one hand, and disease, for the most part in the form of degeneration of some kind from prolonged excess on the other, are of course only too familiar among its effects. Much also has been said of the general depression and disturbance of function which usually precede the establishment of organic disease; of the loss of appetite and craving for stimulants, and even the need of them for immediate and temporary exertion of any kind. But I allude now to none of these. I refer to a state often antecedent to the one last mentioned, of what I would call habitual narcosis—a state due not to a comparatively large excess of alcohol at any one time, but to the daily, almost hourly, imbibition of beer or spirits. Alcohol in some form is taken, not at any one moment in very large quantity, but at intervals so frequent as to keep up its effect in a powerful degree continuously through the twenty-four hours. This habit pervades all classes of society, but it prevails most largely, or at all events it is most openly illustrated, among the lower. I believe that it may be seen most commonly in the carmen who drive slow and heavy wagons through the streets of London. These men hardly ever seem to be thoroughly awake. They sit for the most part bent forward, with a dull drowsy countenance, the eyes either half or wholly closed, and the limbs and body shaking with the vehicle from sheer relaxation of the muscles. If the horses which lead them were not more intelligent, none would dare to venture within their range. This condition is not due to mere fatigue or weariness. The swollen features, the congested surface, the bloodshot eyes, tell another tale. Moreover, when aroused from this stolid state, the behavior is characteristic enough. When suddenly surprised they speak or turn round, but not as one overtired and half asleep, or even naturally very stupid, but only after a prolonged interval, with slow and lethargic action, like the movement of a sloth or tortoise. Perhaps, in civilized life there is no state of human nature lower than this. Here the blood is constantly charged with alcohol, and the brain and other nerve centres are always largely under its influence.

But inevitable as the result is here, when nothing stronger than their own will intervenes to interrupt its course, if from these men alcohol be forcibly withheld for a time, before the stage of serious organic mischief has been reached, they are usually restored very rapidly, and often become changed in a startling way. When such men are brought with some injury into a hospital they are likely to pass through an attack of delirium tremens, from which, however, they usually recover, and the approach of this is made manifest by want of sleep, general depression, and tremulousness. But most of them, if the injury be not severe, after passing a few days in a heavy drowsy state, craving for beer or gin, rapidly grow brighter and fresher, become more alive, and before long are so changed for the better in every way that it must be difficult, I should think, for the patient to believe in his personal identity.

Something is to be learnt from these cases. Formerly it was assumed to be highly dangerous to suddenly deprive a man, who had been accus-

tomed to excess of them, altogether of stimulants. I would not venture to say that this can invariably be done with impunity, but I have no hesitation in saying that as rule the practice is safe and satisfactory. And in the very exceptional instances when danger threatens, it can, I think, be usually foreseen. If a man can sleep and eat tolerably well, his life does not hang on stimulants. Nay, even in delirium tremens, looking to these signs, we may with the best effect often withhold them. I suppose it is well understood now that it is not good practice to prescribe stimulants in delirium tremens as a matter of mere routine. When such patients as these come under our care I would always, when practicable, give them time for recovery from the effects of this bad habit before subjecting them to any operation, or even to measures of severe restraint. The time is well spent in leaving such a patient alone for some days to the influence of suitable food and the rigid exclusion of alcohol in any form, and in standing by and watching the change in the furred tongue and foul breath and obtuse intellect, until at length he may truly say of a demon more potent for evil than that which assailed Macbeth—

Why, so: being gone,
I am a man again.

DIFFUSE CEREBRAL HÆMORRHAGE IN A NEW-BORN CHILD AFTER AN EASY LA- BOUR;

COMMENCEMENT OF SYMPTOMS ON FOURTH DAY;
DEATH ON FIFTH DAY; AUTOPSY.

By F. H. CHAMPNEYS, M.A., M.B. Oxon., F.R.C.P.,

Assistant Lecturer on Obstetrics and Assistant Obstetric
Physician to St. George's Hospital.

MRS. C—, aged about twenty-five, at her second confinement (her first labour having been normal and the child alive and healthy) was delivered easily and naturally on Sept. 8th, 1881, at midday. On the night of the 10th the child was restless. On the 12th, at 9 A.M., it was found in its cot with its hands clenched. At 10 A.M. the child had a convulsion. At 2 P.M. it squinted and became livid, and this squinting and lividity recurred about every twenty minutes. At 10 P.M. there was a strong convulsion, repeated about every hour till 1 A.M. on the 13th. At 11.30 P.M. on the 12th left ptosis supervened, which rapidly increased. From 1.30 A.M. to 4 A.M. on the 13th the convulsions were almost incessant on both sides, but affected the left side most. Death took place at 4 A.M.

The necropsy was made by Mr. J. Kingston Barton (to whom I am also indebted for some of the above facts) under very unfavorable conditions, which, added to the ordinary great difficulty of examining the brain of a newly-born infant, made a more precise examination impossible. Child female; length twenty inches; apparently mature. Heart: foramen ovale closed, except a very small aperture at the upper border; mitral and tricuspid valves showed "hæmato-nodules" described by Parrot, corresponding to his description. Brain: diffuse apoplexy, especially of the left side, the blood having escaped apparently from the neighborhood of the lateral ventricles and reaching the surface in parts; on the convex surface there were many small hæmorrhages.

The hæmato-nodules are thus described by Parrot: "The hæmatomata are little tumours, of

spheroidal or conical form, black or dark violet, like concretions of blood or morsels of coal, varying in size from the smallest size visible to the naked eye to that of a millet seed; isolated or united so as to form little clusters. They are only found on the mitral and tricuspid valves. . . . They are smooth and glistening, and appear always covered by the superficial layers of the endocardium. . . . After a time they become decolorized, sink, and little papilliform eminences alone are found.² . . . They are seen in children immediately after birth and during the first month, but are not seen in still-born children. After the first month they rapidly decrease. . . . They are to be considered as the result of the changes in the circulation at birth.³ . . . They contain blood, of which the hamatin is in various degrees of change.⁴ . . . They do not resemble the products of acute endocarditis. Their surface is always smooth; they are never soft or friable, and can never be detached except by tearing. . . . They never show arborescent vessels; they are not to be regarded as pathological, but as, at most, demilections." I have given this description as exactly describing the appearances in my case. In 120 children under seven years of age Parrot found them in seventy-four. In all of these (thirty) not more than a fortnight old, they were never absent. I may add that I have found them in all the children dying soon after birth, but not in any full-time still-born fetuses in whom I have looked for them. I do not imagine that they had anything to do with the cerebral hæmorrhage.

The case seems worthy of record on account of the rarity of cases of cerebral hæmorrhage in young children; the rarity with which they are recorded may be partly due to the fact of their falling somewhat between the departments of the obstetric and the general physician. It may be scarcely necessary to remind the student of such cases that the term "apoplexy" applied to young children is generally used to describe the first or livid stage of asphyxia. Such "apoplexy" may be associated with true cerebral hæmorrhage.⁵ Rilliet and Barthez⁶ say nothing about cerebral hæmorrhage in the newly-born; the youngest in their table is two years old. Gerhardt, in dealing with the subject of cerebral hæmorrhage in children, mentions its rarity, but calls attention to the fact that the earlier the age the commoner is the occurrence. Four out of twelve cases related by Gerhardt occurred within the first six weeks. Billard found an apoplexy in the left corpus striatum in a child three days old. Berard found a similar one in a child eight months old. It is commoner in males. Rilliet and Barthez give a table in which nine out of fifteen were males. Bednar found eleven out of sixteen in males. It is generally preceded by disease, and may be associated with miliary aneurisms. Inter-meningeal (as opposed to intra-cerebral) hæmorrhages are not rare after difficult labours, and are due to contusion. Capillary "ectasies" are congenital; miliary aneurisms always arise after birth; injuries after birth are usually inter-meningeal. In my case the small cortical hæmorrhages may have been the result of the convulsions.

ON THE SEPARATION AND TRANSPLANTATION OF OVARIAN CYSTS.

By EDWARD MALINS, M.D., C.M.,

Obstetric Physician to the General Hospital, Birmingham.

THE present paper is illustrative of a very uncommon pathological condition, and affords some important and interesting details from a clinical aspect. Five cases have come under my notice where cysts were transplanted to a new situation; in one the separation was not absolutely complete when the patient was operated upon, though the transplantation was advanced; in the three others the union from the place of original development was entirely severed, and a connection established under different auspices with fresh structures. The process by which this was accomplished created much disturbance for a time, but the cysts afterwards appeared to have settled down with a singular accommodation on the part of their surroundings. This toleration after an inflammatory storm has subsided is an interesting feature to note; the contest during the while is severe, the fresh region resents the intrusion of the foreign body, the temperature rises, the pulse quickens, there are pain and constitutional distress. This is continued, with varying doubts as to the issue, for an uncertain time, until the persistence of the invasion overcomes the reluctance of the new locality, and the cyst is retained where accident allots it space. Thus, like a parasite, it ultimately derives its nourishment and fosters its growth from the part which unwittingly accedes to the necessities of the conqueror.

CASE 1.—Mrs. W—, aged forty-five, married twenty years, thirteen children, youngest three years old, was admitted to the General Hospital on July 1st, 1882, with the following history: She stated that she had always had good health until March, 1881, when she noticed an enlargement of the abdomen, chiefly on the right side; this continued to increase in size. Six months later, while nursing and lifting a sister who was ill, she was suddenly seized with violent pain in the abdomen and was obliged to go to bed. This was followed by an attack of inflammation of the bowels, which caused her to keep her bed for several months, she was very feverish and had occasional shiverings. The abdomen became much reduced in size, but still swollen and tender, and in March, 1881, a large abscess formed below the navel, which, pointing outside, was opened by the doctor and several pints of matter let out. This discharged for some weeks and ultimately closed. Still a large lump remained; it was not particularly painful, but she was feeble and unable to work. Menstruation had been regular. On examination the patient was thin but otherwise healthy looking. The abdomen was not tense; a little to the left and one inch and a half below the umbilicus was a depressed cicatrix an inch long. On palpation a rounded mass was felt about the size of a small cocoon, the bulk of which was to the right of the median line, the upper border being a little higher than the level of the umbilicus. Fluctuation was indistinct; it was smooth and evidently adherent to the inner aspect of the abdominal wall. The uterus was free; there was nothing abnormal in the pelvic roof; there was no albumen in the urine. On July 12th the abdomen was opened in the middle line by an incision three inches long through somewhat dense tissue, when a cyst was found adherent to the abdominal wall, the omentum, and on the left to about four inches of small intestine. The adhesions were separated and the cyst removed; there was no pedicle, and on examining the pelvis

the right ovary was absent. The Fallopian tube could not be traced. The patient made a good recovery. The cyst weighed nine ounces and a half, was crinkled, dull, and dense, its walls were an eighth of an inch thick, irregular, and the interior contained about nine ounces of thin grumous fluid. It would appear that there was originally a large cyst; that this, probably containing clear fluid, had ruptured, giving rise to the inflammation of the bowels spoken of by the patient; that the cyst diminished in size, became adherent to the place I have mentioned by the activity of the inflammatory action; that, becoming fixed, it gradually dragged away from its attachment to the broad ligament, this stretching being favored by the constant movement of the intestines, until at last it established itself by a prescriptive right of possession to the new situation it had acquired. Probably as a result of the inflammation of its walls, and in some measure owing to the low vitality, its connection must have permitted, there was free supuration in the interior, which, finding its way in the direction of least resistance, the pus was let out when it showed signs of coming through the abdominal wall. After this there was an abeyance of acute symptoms, but the tumour remained with a future before it upon which we may speculate as probably that of a passive existence.

CASE 2.—Miss S—, aged eighteen, pale, strumous-looking, stated that she was brought up in the country until a year ago, when she came to live with some relatives in Birmingham. Before leaving home she had a bad attack of "inflammation of the bowels," and was confined to bed for some weeks; since then she has never been well and strong. Has been irregular, and suffered from occasional attacks of pain in the lower abdomen and right side; this was always most during menstruation, obliging her to lay by for some days. On Oct. 23rd, 1882, she got wet, and went to bed with indications of an ordinary cold. On the 25th she had a shivering with acute pain in the abdomen. Dr. Lewis was sent for, and the pain relieved by hot fomentations and opium. On the 26th I saw her with him; she then had constant sickness, pain and tenderness over the abdomen, particularly in the right iliac region; quick pulse and high temperature. Per vaginam the uterus was fixed, the pelvic roof hard throughout; by the rectum the pelvic contents were represented by a general hardness, through which definition was impossible. Her urine was free from albumen. On the morning of the 28th she was seized suddenly with an intense aggravation of the abdominal pain, with collapse. The abdomen was distended and exquisitely tender; there were profuse sweating and general torpor, the tongue dry, pulse 130, temperature 102° F. She never rallied, and died on the 29th at 1 p.m. On the following morning a post-mortem was made by Dr. Lewis. On opening the abdomen there were signs of general peritonitis; the intestines were dull, slightly adhering in some parts, more firmly in others, with here and there patches of recent lymph. On the right side of the pelvis the parts were matted together by inflammatory adhesions. To the inner aspect of the cæcum, adhering to it, to the omentum, and to the adjacent coils of small intestines, was a cyst the size of an orange, smooth where not attached, and tailing off with a band like a pedicle into the thickened mass on the right of the uterus, in which by careful dissection no trace of an ovary could be found. The cyst contained between two and three ounces of thick yellow pus, and at its lower part was a small opening through which this had ruptured into the peritoneum. The cyst wall was dark leaden-colored, about two lines thick, denser in some parts than others; and over one side

could be traced a band, which terminated irregularly like the end of the Fallopian tube. The inner surface was roughened and irregular. The left ovary was enlarged, and the Fallopian tube on that side distended and containing pus. The uterus was small and hard, intimately connected by adhesions with the rectum and surrounding parts. Read by the light of this history, the explanation seems to be that this girl had an ovarian cyst, which became adherent during the attack of the so-called inflammation of the bowels a year before; that it subsequently suppurated, and was associated with a condition of chronic pelvic peritonitis; that it became separated and transplanted, eventually ruptured and caused death. That such a state of parts in the pelvis is not inconsistent with a tolerable condition of health and ability to pursue the ordinary avocations of life we have occasional clinical knowledge. One case I remember seeing at the post-mortem of a young person who died of peritonitis after a few days' illness: the ovary was dilated and filled with pus, which had burst into the peritoneum. The abscess of the ovary was evidently of old standing, and yet within a week of her death the patient was going about as usual.

CASE 3.—Mrs. T—, aged thirty-three, fair and healthy-looking, four children, the youngest five months old, came as an out-patient to the General Hospital on Oct. 27th, 1882, with the following history:—She stated that her health had always been good until after the last confinement, when she noticed a swelling on the right side of the abdomen, which was gradually getting larger; it was not painful, and only affected her by the inconvenience of its bulk. On examination, the abdomen was smooth and tense, larger in the right half, fluctuating throughout; no solid matter felt. The uterus was drawn up to the right, and measured three inches; no albumen in the urine. Diagnosed large unilocular cyst of the right ovary. The patient was advised to wean her baby, and come again in a month's time for operation. She was admitted into the hospital on Jan. 5th, 1883, having written to say that she had been detained by a bad attack of "inflammation of the bowels," for which she had been in bed a fortnight; this came on suddenly in the night, after going to bed in her usual health. On examination, I was struck with the change in the appearance of the abdomen from the time of her last visit. Instead of a uniform distension, smooth, tense, and fluctuating, there was now a prominent bulging in the middle of the abdomen, below the umbilicus. This was manifestly adherent to the inner wall, the surrounding parts being lax, and the skin quite loose. It was about the size and shape of a "Rugby" football. On Jan. 11th the cyst was removed. It was adherent to the anterior abdominal wall, the omentum, and to about three inches of small intestine; its lower border was connected by a pedicle which had rotated round from the right forwards, and over to the left for about three turns, presenting the appearance of a twisted umbilical cord. The connection with the broad ligament and right side of the uterus was shelled off by the fingers from an area of organizing extravasation; there was no ovary. The cyst was olive-green colored, smooth externally; it weighed thirteen and a half ounces, and contained seventy-four ounces of port-wine colored fluid; its walls were thick and puckered, its interior irregular. A glass drainage-tube was put in the abdomen and retained for five days, during which time eight ounces of sanguinolent fluid were taken away. The temperature was never more than a little over 99°, and the patient has made a capital recovery. A similar explanation is applicable to

this case from the course in which events were noted with a reasonable probability of sequence. There was a large thin-walled cyst; this ruptured in the night; the cyst collapsed and became twisted round on its pedicle; peritonitis succeeded from the quantity of escaped fluid, then came adhesion, arrest of circulation by the torsion with transudation of blood in the interior, and final separation with transplantation away from the primary source.

CASE 4.—Mrs. P——, aged thirty-three. This case is recorded in *THE LANCET* in 1877. There was a large single cyst which was tapped on Feb. 18th, sixteen pints of fluid being withdrawn; on March 3rd it was removed, the patient making a good recovery. In this case the pedicle was rotated for two complete turns; there were recent adhesions to the omentum, anterior abdominal wall, and small intestine. The cyst weighed 1 lb. 9 oz., was shrunken, dark livid colored, and contained half a pint of dark colored fluid. Here the mechanism by which the result was produced was identically the same. A large single cyst was tapped; it collapsed, drifted from its moorings; under the influence of soft elastic pressure from constantly moving intestines it became twisted round on its stalk; peritonitis gave the conditions for the adhesion which was present, and transplantation was practically complete. The twisted pedicle no longer afforded a link for the vital connection, but, with the principle of true conservative reparation, delayed its final separation, while the cyst was forming adhesions by which it was destined to find an independent existence.

CASE 5.—F. V——, admitted to the General Hospital on Feb. 17th, 1883, with the following history. Has been ill for two years with pain in the left side of the abdomen, which has been gradually increasing in size. Sixteen weeks ago, while sitting still she was suddenly seized with pain in the abdomen; this was followed by an attack of severe inflammation of the bowels, for which she has been in bed ever since. Five weeks ago she was seen by an eminent surgeon, who diagnosed hæmatocoele, and aspirated through the abdominal wall; rather more than six pints of dark-colored fluid, mixed with blood, were taken away. The pain and swelling still continued. On admission the abdomen measured thirty-one inches round; from the umbilicus to the left superior spine, five inches and three-quarters; to the right the same. On Feb. 22nd, the abdomen was opened, and a cyst formed of the right ovary was found adherent to the abdominal wall, the omentum, and about four inches of small intestine. The walls were about one-eighth of an inch thick, and dark-olive-green colored; the cyst weighed 1 lb. 3 oz., and there was about five pints of port-wine-looking fluid in the interior. The pedicle was twisted two and a half times, was friable, and easily disconnected from its attachment, which was in the process of separation. The abdomen was drained and dressed antiseptically. She made a good recovery.

In the cases I have narrated it will be seen that the four operated upon recovered, that there was a close similarity in the history as given in the accounts of the patients themselves, and in the symptoms exhibited. In the remaining one it would have been hopeless to have attempted any operation from the extent of the chronic pelvic peritonitis which was lighted up by the rupture of the pus-containing cyst, and the extreme condition of the patient at the time the consultation took place. That large thin-walled cysts may burst, giving rise to temporary disturbance, and ultimately disappear, is now well known, but that under certain conditions transplantation may take place there

has not been as far as I know any clinical record. In the *Edinburgh Medical Journal* for January, 1861, is a paper by Professor Turner, of which he was kind enough to send me a copy. He there relates a case found in the dissecting room in a woman aged seventy-nine, where an ovary the size of a foetal head was transplanted to the peritoneum covering the first and second lumbar vertebrae. He also quotes an essay by Rokitsansky upon the same subject, mainly setting forth the effect of peritoneal inflammation in intra-uterine life. In a paper on mesenteric and omental cysts by Mr. Knowsley Thornton, in the *British Medical Journal*, December 23rd, 1882, is a case which appears to be in support of my observations; a left dermoid cystic ovary was twisted off from its pedicle and became adherent to the omentum on the right side from which its nourishment was derived.

Birmingham.

A CASE OF LARGE FEMORAL HERNIA,

WHERE SUDDEN RUPTURE OF ITS COVERINGS OCCURRED, AND A PORTION OF INTESTINE WAS PROTRUDING FOR SEVERAL HOURS BEFORE REDUCTION.¹

By BERNARD PITTS, F.R.C.S. Eng.,

Assistant Surgeon, St. Thomas's Hospital.

THE following case is a very unusual one. I have not heard of any similar accident. It is also certainly rare for recovery to take place when the intestine has been so much manipulated and so long exposed. The patient was admitted last December into St. Thomas's Hospital, into one of Mr. Mason's beds. I operated on her as a case of urgency. I am indebted to Mr. Mason for allowing me to continue in charge of the case.

Frances V——, aged forty-six, a laundry-woman, has suffered from a right femoral hernia for twenty years. She wore a truss till three years ago. On Aug. 30th, 1880, she was admitted into Guy's Hospital with symptoms of strangulation of three days' duration. She had not worn a truss for a year previously. An operation was performed by Mr. Jacobson. The sac was very thick and intestine dark. She left the hospital on Sept. 27th, wearing a truss. The hernia at the time of operation was about the size of two fists. For one year after this she kept up the hernia with the truss, but subsequently the great increase in the size of the hernia rendered the truss useless. During the last winter she has suffered from a bad cough, and the hernia became as large as a child's head, but always reducible. Several small ulcers formed on the skin, which caused her to leave the truss off altogether. About nine o'clock on the evening of the 4th of last December the patient was going upstairs in her home at Kennington, when, whilst sneezing violently, she felt something give way suddenly in her right groin. She became very faint, but managed to walk to her bedroom, and then discovered that about a foot of intestine had escaped through a rent in the coverings of the hernia. She made an attempt to return it, and sent for her medical man, who tried taxis for a short time, and then advised her removal to St. Thomas's Hospital. She was brought to the hospital in a cab on a cold and frosty night. I saw her directly on her admission at twelve o'clock. She was an extremely stout woman, and suffering then from severe shock. An examination under ether was at once made on the bed, and one foot and a half of small intestine was found protruded through a rent in the skin, about an inch long, and situated a little above the old

¹ Read before the Medical Society of London, Feb. 19th.

operation cicatrix. There were one or two chronic, small ulcers to be seen on and near the lower part of the cicatrix. The exposed intestine was bruised, congested, dirty, and very cold. A number of hairs and foreign particles were removed from the bowel and mesentery, which was then carefully cleansed with warm carbolio lotion. Failing to get the bowel back by taxis, the opening in the skin was enlarged freely, and a large quantity of small intestine escaped from the sac, at least four or five feet, together with the cæcum. A slight enlargement of the crural ring was made with the hernia knife, and by patient manipulation the intestines were returned into the abdominal cavity. A sponge was placed in the opening, and the very thickened sac was dissected from its surroundings and removed; this involved the ligature of a considerable number of vessels. The sponge was then removed, drainage for the peritoneal cavity provided, and the cut edges of the sac brought together by very stout catgut. A large portion of redundant skin (including the cicatrix and the ulcerated parts) was then removed, and the edges of the wound brought together by silk sutures, and the wound dressed with carbolio gauze. The patient slept a little during the night after a subcutaneous injection of morphia. On the morning of Dec. 5th the wound was dressed, the temperature being 100.4°. In the after-part of the day the breathing became very labored. Pulse 132; temperature 102.4°; great lividity of countenance. She was propped up in bed and brandy administered. The urine was found albuminous. The subcutaneous injections were discontinued.—6th: Breathing decidedly better, but cough very troublesome. Temperature normal. The wound was dressed and the abdominal drain removed. After this she made a slow recovery, the temperature never reaching higher than 100°. She has been for some time convalescent and is wearing a truss.

Remarks.—It certainly seems difficult to understand how such an accident as happened to this woman was possible. By a mere effort of sneezing a thick sac and free movable, though stretched, skin were split. The rent had much the appearance of an incised wound; it occurred at a part where the skin was perfectly sound, but close to the cicatrix of the former operation. I imagine this would be a point more likely to give way than the cicatrix itself, because it was the junction, as it were, of the new cloth with the old, and where the movable part of the skin joined the adherent. The case is interesting also in a medico-legal aspect, for supposing the patient had been unable to give an account of the occurrence, suspicion of violence must necessarily have arisen. In the treatment of the case the most important point was to thoroughly cleanse the protruded parts and then to get them back as quickly as possible into the abdominal cavity. In order to avoid increase of shock I operated on the bed at the time of the examination of the patient, and did not use the spray. Drainage of the peritoneal cavity was provided, because it was thought that some peritoneal inflammation might necessarily be expected. The latter part of the operation—viz., attempting a form of radical cure—occupied a good deal of time, and must undoubtedly have increased the shock to the patient, but was necessary on account of the very violent cough from which the patient was suffering; and, moreover, the woman is now in a much better condition than she was before the accident occurred. The hernial opening is now perfectly under the control of a light truss, and with proper care the hernia ought never to attain to anything like its former inconvenient dimensions. I believe also, that by getting rid of a large sac and redundant skin, the chances of continued

suppuration are much lessened, and where there is a large hernial opening, the ligature of the neck of the sac diminishes the danger of inflammatory extension from the wound to the peritoneal cavity.

When the sac has been opened in cases of strangulation occurring in large umbilical and scrotal herniæ especially, a great deal of improvement in the after-condition of the patient may be effected by taking redundant parts freely away. In August, 1881, a man was under my care with a very large femoral hernia, the largest I have ever seen, quite as large as a man's head. It had been irreducible, and was of about the same size for many years. I had to open the sac for symptoms of obstruction. After taking away a quantity of omentum, and replacing the intestines, I dissected out the sac, removing a portion of sac and skin corresponding, which measured about thirty inches in circumference. I was fearful at the time whether the abdomen would tolerate the continued presence of so much intestine that had been in the habit of dwelling outside. The man made a good recovery. I have seen him frequently since, and he has been able to keep up the rupture with his truss. He has therefore parted with a most inconvenient burden. The sac in a very old-standing hernia is so thick that union of its edges forms a very firm support. The success that followed in this case determined me to pursue a similar course in the case here recorded.

CASE OF RAPID ACUTE MENINGITIS, WITH DEATH.

By ERNEST F. NEVE, M.B. Ed., M.R.C.S.,
Resident Physician to Cowgate Dispensary, Edinburgh.

On Tuesday, Nov. 28th, 1882, I was called to visit G—, a girl aged about eight years. None of the past history in the least concerned the present illness; the child had been perfectly healthy, although exposed to great vicissitudes—want of food, cold, etc. The immediate previous history was as follows. In the morning of the day of my visit, on rising, the child complained of a slight pain in the left side of the neck. As she soon ceased to complain, the mother paid but little attention to her. During the morning the child was running about, and seemed, as the mother said, perfectly well. In the middle of the day she lay down on the bed and fell fast asleep. About two or three hours afterwards, the mother, who wanted to go out, found some difficulty in waking her; she seemed drowsy, spoke indistinctly, and was indisposed to move. However, she got up and went out at 5.30 p.m. and sang in the streets till 7 p.m. It was a very cold day. About that time the child left her mother's side to get change for sixpence, and did not return. After ten minutes' time the mother went in search of her, and found her lying on a door-step unconscious and somewhat delirious, talking about "sugar-candy, and all kinds of things." A bystander put the child into a cab, and she was conveyed home. The mother says that she remained in the same condition till I saw her at 9.30 p.m. She was then lying on her left side, with the knees and arms flexed and drawn up, and the muscles of the neck contracted. The cheeks were slightly flushed, the expression of the face that of repose, the eyes closed, not tightly. There were no movements of the muscles of the face; the head was warm, but not hot; the temperature was 100.5° in the axilla; the body felt hot, the feet and hands cold; the respiration was regular and deep, not stertorous, 25 per minute; the pulse was 100 per minute, extremely feeble, and hardly perceptible.

the cardiac impulse was also excessively weak. The left pupil was widely dilated, the right markedly contracted; both reacted to light, and the left contracted when a light was held before the right. The child was quite unconscious. When moved over on the right side, however, she groaned. When the head was firmly touched, or the neck moved, she said once or twice, "Oh, dear!" and moved her hands up as if to remove the annoyance. There was no evidence of either fracture or bruise on examination of the head. I ordered a blister for the left side of the head, a drastic purge of jalap, and hot bottles to be applied to the feet.

The child's death, which occurred next morning at 9 A.M., was immediately preceded by two or three convulsive fits. After one of these I am told that she vomited some yellowish material, possibly the powder administered the previous evening.

Autopsy, thirty hours after death.—This was refused by the mother. I declined giving the certificate, and the authorities appointed Dr. H. D. Littlejohn to perform it. I was present. The dura mater was firmly adherent to the calvaria at a great many points. When reflected the veins of the surface were much distended with blood. The dura mater was not adherent to the arachnoid. There was a distinct infiltration of purulent matter under the arachnoid, over the cerebral convexity, occupying especially the spaces between the convolutions and extending round to the base. On removing the brain, there was found at its base about half an ounce of sero-purulent fluid, with here and there a puro-fibrinous deposit; this existed especially around the optic nerves. There was no macroscopic evidence of tubercle. The pia mater was injected but not tough. The cortical substance was rather soft. There was scarcely any fluid in the ventricles and no further evidence of any lesion.

Remarks.—The chief points of interest in the case are:—1. The rapidity of the onset of the disease and the absence of prodromata, except the slight cervical pain. 2. In the character of the first stage there was a marked absence of the usual symptoms. There was no twitching of the muscles, no vomiting, no evidence of paralysis, even of the third nerve, except as far as the dilatation of the pupil on the left side was concerned. When seen at 9.30 P.M. the temperature was 100.5°. There was no ground for supposing that the child had a headache. The child, according to the mother's account, remained in the same condition during the night. 3. She seems to have passed into the comatose state the following morning, this condition being preceded by the convulsive attacks and vomiting. After an extremely brief duration of this stage she died in a convulsive fit, according to the account of the mother.

Whether the disease had been latent for some days and the mother inattentive to the child's condition, I cannot say. I can see no evidence to lead me to consider it a case of exacerbation of pre-existing tubercular meningitis. The evidence, such as it is, points, I cannot help thinking, to the exposure to cold as the exciting cause of the disease.

Edinburgh.

A NOTE ON THE CURABILITY OF CEREBRAL ANEURISM.

By JAMES GREY GLOVER, M.D.

It is always a pleasant thing to record recovery from the gravest lesions, even when nature has all the credit of the cure. For this reason I publish the

following part of a letter received some time since from a medical friend in the United States in reference to the death of a dear relative. I do so with the more satisfaction, as Dr. Welch, of New York, is the pathologist answerable for the post-mortem examination. I need make no apology for the letter-like form in which the facts are vividly expressed:—"—died of an aneurism of the internal carotid artery. Nine years ago she had an aneurism of the internal carotid artery, which ruptured; the blood extravasated at the base of the brain was absorbed, and she recovered—a thing unknown, spontaneous cure of aneurism of internal carotid. She then enjoyed nine years of uninterrupted good health. A second aneurism developed near the old one, just as the vessel leaves the carotid canal at the base of the brain, within the cranial cavity, of course. The only symptom she had during her illness was paralysis of the third cranial nerve. We had hoped this paralysis was functional, not suspecting an aneurism, and never having fully understood the nature of the cerebral trouble nine years since. She was perfectly well until three weeks before her death, when she was taken sick. She suddenly became unconscious, and remained so for twenty minutes. She came out of this, and the attack passed off, leaving only ptosis, dilated pupil, and strabismus. Ten days later she had another attack, similar to the first, but more severe. From this attack she rallied, but the third attack followed. She became suddenly unconscious, and remained so fourteen hours. When she died Dr. Welch made the autopsy, which revealed the aneurism which had ruptured, and the obliterated sac of the old aneurism which ruptured nine years ago. This, I believe, is the only case of its kind on record."

CASES ILLUSTRATING THE SURGICAL DISEASES OF CHILDREN FROM THE HOSPITAL FOR SICK CHILDREN, PENDLEBURY.

By G. A. WRIGHT, M.B. Oxon., F.R.C.S. Eng.,

Surgeon to the Hospital, and Assistant-Surgeon to the Manchester Royal Infirmary.

CASES OF NECROSIS OF THE PATELLA LEADING TO DISEASE OF THE KNEE-JOINT.

CASE 1.—Ambrose C—, aged eight years, was admitted in December, 1881. In June of the same year he fell from a wall, but did not feel any serious ill effects till a month later, when his knee swelled and he became lame; there was also some redness and tenderness about the joint. Under treatment his condition improved, but he had not got quite well when, five weeks before admission, he was kicked upon the same knee, fresh inflammation was lighted up and an abscess appeared which discharged three weeks after the second injury. His general health somewhat failed, but he had no great amount of pain and no night startings. On admission he was a not unhealthy-looking boy. The right knee was considerably swollen, but the swelling was almost entirely limited to the tissues around the joint, there being but little effusion apparent within it. Three sinuses were seen on the front and sides of the knee, and these freely communicated with one another. A few days after admission the sinuses were slit up and drained and the limb fixed upon a back splint. He did fairly well for a week, when the knee became more swollen and tender, and the boy's temperature rose to 102°; the superficial wounds were then swabbed out with chloride of zinc, and the joint freely laid open on each side. The incisions gave exit to a considerable quantity of lymph and

flaky serum. The synovial membrane was swollen, but the cartilage seemed healthy except at one circular spot, about half an inch in diameter, in the centre of the patella; here a perforation existed which ran completely through the bone and communicated freely with the openings on the front of the knee. The wounds were dressed antiseptically and pressure with sponges employed. Some burrowing of pus took place a few days later in spite of apparently free drainage. Counter-openings were then made, and the case went on fairly well, though it was questionably aseptic; the openings, however, never healed, and the sinuses assumed that indolent intractable character so common in cases of chronic joint disease in children, and in spite of various modes of treatment, the boy at his discharge was not in a satisfactory condition. He was sent to the seaside in an immovable apparatus, and allowed to get about with crutches, but was finally lost sight of.

CASE 2.—John —, aged seven years and three months, was admitted in July, 1882. Ten weeks before he was first seen he received a blow upon the left knee, and the joint became painful and weak from that time, but there does not appear to have been any acute inflammation, and it did not discharge until five days before he came to the hospital. His health had not been so good since the accident, and there was a family history of phthisis. On admission the left knee-joint was found to be swollen and fluctuating, the swelling mapping out the synovial sacs, and bulging in the popliteal space. The skin was somewhat red, and the veins were turgid, but there was very little tenderness. A sinus, which was scabbed over, was seen over the front of the ligamentum patellæ. The limb was in good position. Six days after he came in the sinus was explored, and found to lead to the upper surface of the patella. On laying open the track a sequestrum of the size of a damson stone was found loose in the centre of the bone, and on removing it a perforation into the joint was seen. The joint was laid open freely on each side, and the finger could then feel the orifice on the articular surface of the patella, corresponding to the external opening. Much thin serous fluid and solid creamy masses of coagulated lymph were squeezed out of the joint. The operation was done under carbolic spray, and rubber drainage-tubes and sponge pressure employed with the usual dressings. The temperature did not reach 100° after the second day from the operation, and he was discharged with a small superficial wound at the end of August, eight weeks after admission. Soon after his discharge passive movement was attempted, but there was still a good deal of swelling about the joint, and not much progress was made. In October he was put under chloroform and the joint examined; it was found that very firm and extensive adhesions had formed within the joint, and it was finally decided that these and the continued thickening of the tissues made it wiser not to attempt anything better than a straight stiff limb, especially as the remains of the patella were fixed somewhat firmly to the femur. The wounds were all at this time soundly healed. He was seen again in January, 1883, and the limb remained in much the same condition, a good deal swollen, but painless and slightly movable. The wounds had remained sound.

Remarks.—In *THE LANCET*, in 1878, Mr. Gay records a case in which he removed the whole patella for necrosis. In this case the bone was apparently bare, except that a portion of the articular cartilage remained undetached. Mr. Gay gives references to four other cases: (1) That of Thirion of Namur; here, too, the whole patella in a young subject was removed for necrosis after a fall, the

patient being of strumous constitution. In this instance, as in my cases, the patella appears to have been perforated, though a much larger part was removed than in my patients. The joint was found full of granulation tissue, and the limb ultimately was apparently in nearly the same condition as in my second case.¹ (2) Knöde, of Missouri, published a case in which after a fall on ice some sloughing of the skin, and ultimately necrosis of the patella, followed. The whole bone was removed, the cartilages of the joint at the time of operation were apparently normal, and the limb recovered a great part of its natural mobility. (3) Mr. Wood, of King's College, removed the whole patella as a loose sequestrum from a girl aged seven. Here the necrosis was pyæmic. (4) Dr. Gross, of Philadelphia, has also removed the patella for necrosis after frostbite. The patella has also been excised for dislocation of the bone, with consequent pain and uselessness of the limb. Mr. Erichsen, in his book, mentions a case where necrosis of part of the patella followed a fracture, and the sequestrum was removed by him with good result. I can find no cases other than those recorded. Periostitis of the patella from injury resulting in exfoliation is, I imagine, not a very rare condition; and though I have not found a record of a case, I have been informed by Mr. Clegg, one of the house-surgeons at the Manchester Infirmary, that he remembers seeing an instance at the out-patient department some eighteen months ago. Syphilitic periostitis is certainly not very uncommon; two well-marked cases I have seen myself, but these were not followed by necrosis. I have not, however, been able to find any record of cases corresponding exactly to mine, where, it appears, osteomyelitis of the ossifying nucleus of the patella occurred, leading simply to circumscribed perforation of the bone, and consequent destruction of the joint. The opening in each case was singularly defined and circular, and surrounded apparently by healthy cartilage. In the first case the opening was small, perhaps half an inch in diameter, and probably the whole of the ossified part was not destroyed; no actual sequestrum was found. In the second case a sequestrum was removed, and the perforation was somewhat larger than in the first boy. The condition I have ascribed to osteomyelitis, and this I think most probably correct. I should compare it to the common epiphysitis we see in children; it is, however, no doubt quite possible that the primary condition is periostitis, which, from the greater vascularity of the ossifying centre, affects the bone rather than the adjoining cartilage. There was no reason to suspect a syphilitic taint in either case.

I am indebted to the resident medical officer for the notes of these cases.

ON THE FORMATION AND PREVENTION OF BEDSORES IN NERVOUS DISEASES.

By THOMAS BROWNE, M.D.,

Staff Surgeon to the Royal Naval Hospital, Great Yarmouth.

(Communicated by the Director-General of the Medical Department of the Navy.)

In the following paper on the formation and prevention of bedsores I will first refer to some of the views put forth to explain their occurrence in connection with diseases or lesions of the nervous system.

Sir James Paget long ago pointed out that sloughing of compressed parts is peculiarly rapid and

¹ Vide *THE LANCET*, 1820.

severe when those parts are deprived of nervous force by injury of the spinal cord or otherwise. Charcot refers to experiments made on animals where ulceration occurred in parts paralyzed by section of their nerves, and quotes the observation of Brown-Séquard that these ulcers or sores are produced by prolonged pressure and the contact of faecal matter and decomposing urine to which the parts are exposed. He adds, if the parts are carefully and effectually protected from injury, lesions whose consequence is the abolition or suspension of the action of the nerves are impotent to produce in distant parts other nutritive disturbances than those attributable to prolonged inaction. Drs. Bucknill and Hack Tuke say that the formation of bedsores depends on the cessation of nutrition and consequent death of the tissues, and the blood contained in them, from obstruction of nervous force; and they mention some cases of general paralysis of exceptional severity where the thick fleshy cushion of the gluteal and lumbar regions were extensively involved in a way that bore a strong resemblance to traumatic gangrene. In these cases the slightest pressure produced sloughing: the weight of one leg crossed over the other in bed, or the weight of the hand or the forearm lying on the abdomen. In such cases as these, decomposition had set in while the vital functions were still languidly performed.

As a loss of mere sensation or motion will not of itself produce bedsores, it has been suggested that a lesion of the sympathetic and vaso-motor system of nerves might explain the rapid formation and extension of these much-dreaded sloughs. I may say, in passing, that the sympathetic system of nerves has in later years risen into importance and prominence. Its functions are not well understood, so that we are apt to look on it somewhat in the light in which a commander-in-chief does a good staff officer whose duties are ill-defined, but who is quite ready to be saddled with any odd job that seems to belong to no one else. We know that neuro-paralytic hyperæmia, however far it may go, is never of itself sufficient to cause an alteration in the nutrition of tissue. It predisposes to inflammatory action, and this is lighted up by causes which would be comparatively trifling in a healthy organism. Charcot expresses in strong language the opinion that the formation of acute bedsores depends on lesions which determine either in the nerves or nervous centres an exaltation of their properties, an irritation or an inflammation. He says they develop especially in those regions which are subject to pressure, to friction, or to prolonged contact with urine; but they may also make their appearance apart from these conditions, although the cases are rare. This view is concurred in by Mickle, who says the tissues melt down more rapidly or slough under acute trophic disorders of central or spinal origin.

In the course of this paper I trust to be able to show that bedsores, in nervous diseases, at any rate; except in very rare instances, may be entirely avoided. As my experience in the successful prevention of bedsores has been nearly confined to cases of general paralysis, my remarks will chiefly have reference to that disease, though I hope some useful deductions or wider application may be drawn. In general paralysis bedsores were formerly of common occurrence; indeed, towards the closing scenes, they were nearly the rule, their appearance was looked on as inevitable and a matter of course, hardly calling for observation or record. Some very dreadful pictures are drawn by various authors of their character and extent, as well as the septic poisoning that followed, till the patient became a mass of sloughs, a foul and offensive object to all about him. Happily, in

later years a great improvement in this respect has been effected by all who have had the care of such cases, till a bed sore is now the exception in patients dying of general paralysis. Those who have seen much of this disease knew well how profoundly the vital powers are lowered towards the end of a long case. Though healing may, and often does, rapidly occur in the less advanced stages, yet when the last stage is reached how slight is the hope that a bed sore will ever heal. I mean in that condition where the patient lies helpless, speechless, paralyzed in every limb, just able to swallow the food placed in his mouth, apparently insensible to all around him, and quite unconscious of the performance of the natural functions. There is little or no response to any stimulus; with a lowered temperature the circulation creeps sluggishly on, having barely strength to reach the more distant parts of the body, so that if at any point it meets with the most trifling obstacle it simply stops. There is then, as Bucknill and Tuke express it, a "cessation of nutrition, and the consequent death of the tissues and the blood contained in them." In this condition bedsores are very apt so form unless the greatest care is observed. But there is another phase of the disease in which bedsores occur with readiness, where all our skill and attention will be fully taxed to prevent their formation—namely, during those nerve-storms in general paralysis, often recurring and of varying intensity and duration, which arise in connection with the epileptic fits so common in this disease. Here everything is the reverse of the foregoing dull picture of inert life, failing powers, low temperature, and languid circulation. There is, on the contrary, an exalted condition of everything, except to external impressions. There are high temperature, rapid pulse, and frequent convulsions, combined with profound insensibility, lasting it may be for days. The difference between these two states has been often pointed out, and is very marked; and each of them has a bed sore with a distinctive character. In one the sloughs are slow in formation, have little or no inflammation, appearing after prolonged pressure, as if the result of functional inaction alone. In the other the lesions are rapid in formation, and are ushered in by the appearance of blisters or other signs of irritation or inflammation. One consists of passive lesions; the other of trophic disorders. In each of these varieties there is something more than mere trophic change, as these sloughs only occur where pressure is added, and not, as in necrosis or ulceration of the cornea, following some injuries or diseases of the trifacial nerve.

For the prevention of these lesions I have nothing new or startling to introduce. I will only plead for a more careful application of those general principles which guide us in the treatment of other affections, modifying and adapting them to the special requirements of the condition before us. In the first rank may be placed careful feeding, cleanliness, diffusion of pressure, and the maintenance of an equable temperature in the extremities by the application of artificial heat where necessary. By careful feeding I mean a liberal mixed animal and vegetable diet of an ordinary character. So long as a patient is able to masticate, and can safely swallow his usual food, it is best for him to do so, for the digestive functions seem to last after all else is a ruin. When the paralysis has advanced too far to allow solid food to be given with safety, a liquid or semi-solid dietary must be substituted. But it must not consist too exclusively of an animal diet, there must still be the due proportion of vegetable matter, and vegetable juices. Such can be easily and pleasantly given

in soup, which should ever form part of the diet of a general paralytic.

In most of the books to which I have had access it is assumed that it is quite impossible to keep general paralytics clean and sweet. In my experience this is not so, but careful feeding is necessary as well as the most scrupulous and constant cleanliness to preserve a healthy skin. Probably a diet such as I have referred to may do its share towards keeping the skin sweet. We are all familiar with the disagreeable effect of an excessive animal diet on the skin of a dog. Perhaps our anxiety to sustain the vital powers and the view that a general paralytic in his last stage requires a generous diet with a liberal supply of port wine, may lead at times to the exhibition of a diet too purely animal, and in some measure accounts for the skin becoming dull, dirty, and greasy, despite ablution.

I have made little reference to the use of alcohol in the diet of a general paralytic, because I have a decided opinion that it can seldom be a desirable addition to the diet of a patient laboring under such a disease. It is suggested by some writers that chloral, so often useful in this disease, has a depressing effect, and that it is well to give alcohol in some form or other to obviate that result. But careful observations have shown that the pulse, as estimated by the finger, is not lowered by a moderate dose of chloral. The omission of alcohol in every form from the diet and medicine of patients suffering from general paralysis has been attended with no ill result. The experience gained at this hospital agrees with the observations of those writers who have recently stated that as the consumption of alcohol was reduced, the necessity for chloral greatly diminished, so that now in many hospitals the administration of chloral or other sedative is quite exceptional in cases of general paralysis.

I will now discuss the question of cleanliness, and how it may be most effectually attained. A high authority, referring to general paralysis, says, "They must not be allowed to lie in bed; they must be taken out of bed and thoroughly washed, for in the advanced stages it is difficult to keep them dry, and must sit day by day in an easy chair. If allowed to lie in bed, they very soon contract bedsores." My own experience differs much from this. In the paralyzed and absolutely helpless condition of a patient such as I have sketched when discussing passive bedsores, a mere inert living object, it would hardly be possible to keep him in any form of easy chair. Even did we succeed daily in dressing him and placing him in a chair, he would frequently be wet and dirty, for these patients follow no rule when the helpless stage is reached, and no attention is paid to the action of the bladder and bowels. Besides, the pressure caused by mere body weight in the most easy of chairs for three hours would be sufficient to cause a cessation of nutrition, and consequent death of the tissue on which the pressure fell. Its feeble life would be crushed out. A patient in such a condition is, in my opinion, best in bed, for only there can absolute cleanliness be observed. The patient must frequently be placed in a warm bath, gently washed, and carefully dried by the pressure of the towel, not rubbed, as the vitality is too low for that. There must be no hesitation about changing the patient when merely wet, as urine in contact with the skin acts like an escharotic, destroying its vitality like a blight. If the paralysis is far advanced and the patient helpless, he must be placed on a water-bed on which several layers of blankets and sheets have been laid, and in addition to this, especially during the periods of nervous exaltation and insensibility, his feet, ankles, knees, trochanters, sacral spines and ears,

etc.—in fact, wherever there is pressure—must be protected by cotton-wool padding, so as to diffuse the pressure as much as possible. But in the lowered vitality and nearly stagnant circulation, or whilst the nerve-storm and epileptic condition lasts, this is not enough. Even with all these precautions a bed sore will form wherever pressure occurs, unless the patient be frequently moved, turned from side to side, or the point of pressure varied, in severe cases every hour by day, and every three hours by night, if the patient sleeps. The frequency with which the position is varied must be judged in each case. Special care in padding and frequent change of position are called for during epileptiform and apoplectic seizures, and for some days after their cessation.

The extremities must be examined from time to time and their temperature sustained, if necessary, by the application of warmed flannel or hot-water bags, carefully guarded. Hot-water bags, not bottles, must be used; the former act as padding and diffuse pressure, while the bottles, being hard and resisting, would soon produce the sore we dread so much.

I have made no reference to local astringents or other preventive measures beyond cleanliness and padding. Every medical man has his own favorite application. Most of these are good of their kind, so long as they do not divert our attention from the more general measures necessary, and conceal from view the actual condition of the skin till, perhaps, irreparable mischief has been done. Such, then, is the means by which the formation of bedsores has been successfully avoided. Under gradually improved nursing and careful dieting, bedsores became more and more rare, till they finally disappeared, I hope for ever, from the Royal Naval Hospital, Great Yarmouth. For a period of over four years, under various medical officers, there has been an entire freedom from these distressing complications, though there is a larger proportion of general paralytics here than in any other hospital in the United Kingdom. Some of these cases have been in a helpless, speechless condition, paralyzed in every limb and confined to bed for four or five years, yet there is not an abrasion on their skins, and they are free from all unpleasant odor, and have not become "dull, dirty and greasy despite ablution." Such success can only be attained by the hearty and intelligent co-operation of a staff of good nurses and attendants on the sick, who take a pride in their work and in the state of their patients. We are so fortunate as to have secured such co-operation in this hospital. It is always a pleasure to go into the wards and see the care and kindness so heartily bestowed on these most helpless and miserable cases. Should even a spot of redness appear on any prominent part the attendant is full of anxious thought and busy with little contrivances for the removal or diffusion of pressure, equally ready to carry out instructions or make suggestions such as a ward experience soon teaches any nurse worth having. For the prevention of bedsores a good nurse, with the faculty for taking trouble largely developed, is, above all things, necessary.

I will not be so dogmatic as to say that bedsores are always, and under every circumstance, preventable. I can easily believe in such a profound trophic change or degeneration of the tissues, such a depressed vitality with molecular death before the heart and lungs cease to act, as indicated by a cadaveric smell days before life, at last, flickers out, that, do what we will, the epidermis becomes abraded, and the discolored, inelastic, and already decomposing skin yields and breaks down before every touch. I have never seen a case like this, but I think I have several times seen a condi-

tion not far removed from it in the last twenty-four hours of the life of some of our general paralytics.

OBSERVATIONS ON THE USE OF THE CATGUT LIGATURES.

By E. DOWNES, M.D. Brussels, L.R.C.P. Lond.,

Medical Missionary of Kashmir.

IN THE LANCET in 1881, appeared a paper by Dr. French on the above subject. Dr. French, after recording a case of Mr. Barwell's, published in THE LANCET of July 30th, in which hæmorrhage occurred when the ulnar artery had been tied, and was attributed by Mr. Barwell to the use of a thick catgut ligature, proceeds to give his own experience, which goes far to prove (if proof is still wanting) that the catgut is the best substance for the ligature of arteries. At the same time, Dr. French had observed secondary hæmorrhage on one or two occasions when he had ligatured vessels on the human subject; and on one occasion when he experimentally tied the femoral artery of a dog. He thinks the hæmorrhage may have been due to using a thick ligature, and advises the use of a thin ligature. He says: "To those who are in a position to carry out experiments, I venture to suggest the advisability of determining whether, in many cases, the secondary hæmorrhage is not chiefly due to the employment of catgut ligature of too large a size." I determined to undertake some experiments to satisfy myself on this point. I may say that, with some little experience with catgut ligatures in surgical cases, I have never once had a case of secondary hæmorrhage. I ordered ten healthy dogs to be procured, and determined to tie the femoral arteries of these animals. I had procured catgut ligature from Messrs. Weiss, of London, a year ago. On the bottle they were described as four kinds, the numbers being "0, 1, 2, and 3, as used by Professor Lister." I could only distinguish three kinds; probably the two smallest kinds were much alike, and, having been well soaked in oil, I really could not distinguish them; I therefore called the three kinds which I could distinguish large, medium, and small respectively. The dogs were put under chloroform, and the operations were performed with strict antiseptic precautions. One dog died under chloroform, though every precaution was taken. I may mention that I have observed what I have never seen mentioned elsewhere—viz., that dogs and foxes, and probably all animals of this kind, are easily killed by chloroform, far more easily than human beings. So nine dogs only were operated on; three had their femoral arteries tied with the large, three with the medium, and three with the small catgut ligature. The dogs tore off the dressings from the first day to the third, but some of the wounds healed by first intention; in the other cases the edges of the skin gaped, but there was no suppurative in any case, nor was there any secondary hæmorrhage. I need hardly say that I cut the ends of the ligatures short and closed the wounds with fine catgut sutures. I intended to have killed all these nine dogs three weeks after the operations, but the hospital servants begged for the life of one dog so that he might be kept as a watch dog for the establishment. I consented; so only eight dogs remained to be killed and examined post mortem. The dogs were allowed to live over three weeks. Three had been operated on with large, three with medium, and two with small catgut; the fortunate dog having been operated on with the small.

The result of the post-mortem examinations was

as follows:—1. Large ligature; artery quite blocked; walls of vessel uninjured; no mark left by ligature. 2. Large ligature; artery quite blocked; walls of vessel uninjured; no mark left by ligature. 3. Large ligature; artery nearly blocked, but apparently a small channel open; walls also uninjured. 4. Median ligature; artery quite blocked by a very firm clot; walls quite uninjured. 5. Median ligature; artery closed by a small clot, but channel impervious; walls of artery uninjured. 6. Median ligature; channel quite open; a little roughening in one place of the inside of the vessel, perhaps the remains of the clot; walls uninjured. 7. Small ligature; walls of artery nearly cut through by ligature, but artery thoroughly blocked above. 8. Small ligature; the most complete obliteration of the artery for the distance of about half an inch; walls quite uninjured. In no case was any trace of the ligature to be found; it had in every instance been completely absorbed.

I should mention that in tying the vessels I used three twists, as recommended by my old instructor Mr. Lane, of St. Mary's Hospital, instead of the two twists of the ordinary reef knot. It will be observed that this would make the knot still larger than it would have been, and, according to Dr. French and Mr. Barwell, this would increase the danger of secondary hæmorrhage. Notwithstanding this, I did not have secondary hæmorrhage in any case. The only instance in which the wall of the vessel was injured was a case in which the finest ligature was used. I think that with such fine ligature too much force in tying the knot should not be employed. Probably in my case the vessel would not have been injured had I been more careful; but I used as much force as I should have done with a silk ligature when I wished to cut through the inner coat of the artery. My conclusion is that Dr. French's idea that the small ligatures are safer than the large ones is not correct. I also think that with large ligatures the third twist in the knot is an important precaution. I also feel sure that with large ligatures especially it is most important that thoroughly reliable material should be used. If large ligatures are used moderate force should be employed in tying the knot; but if fine ligatures are used I think it inadvisable to attempt to cut through the inner coat of the vessel.

Kashmir.

ON AN INFECTIOUS ULCERATIVE DISEASE OF SKIN AND MUCOUS MEMBRANE CAUSED BY A SPECIFIC BACILLUS.

By ALFRED LINGARD, M.R.C.S., and

ERNEST E. BATT, M.R.C.V.S.

A DISEASE of the above character having yearly caused considerable ravages among young cattle in this country, portions of the affected organs were received by us at the Brown Institution for examination.

The following are a few points we wish to make known prior to the completion of the research, which is so far advanced that it will shortly be published in full:—The tongue and mucous membrane of the cheeks are the usual localities of the primary lesion. The typical ulcer in advanced cases consists of a sore with free, overhanging edges. On section through the sore, the tongue is found to be necrosed to a considerable depth opposite all parts of the ulcer. Wherever the sore touches any other part of the mouth or cheek, the disease is communicated and rapidly spreads. In some cases similar necrotic changes had taken

place in the lungs. The line of junction of the necrotic with the healthy tissues was found to be occupied by a mass of bacilli having the appearance of a dense phalanx advancing upon the healthy tissues. The disease has been proved capable of transmission by the bacilli in question, which are equally numerous and virulent after passing through several generations by inoculation.

CONCERNING THE EFFECTS OF DILUTION AND CONCENTRATION ON THE ACTION OF POISONS.

By SYDNEY RINGER, M.D.,

Professor of Medicine at University College.

THE persistence of the effects of drugs varies considerably. For instance, very soon after discontinuing the administration of chloroform consciousness returns, whilst after dropping into the eye a minute dose of atropia the pupil remains dilated for days. It is evident, then, that the changes induced by chloroform on the brain are obviated much more readily than the changes induced by atropia in the structures of the eye.

From experiments with the frog's heart, presently to be described, I find that the effects of one drug that completely arrests function are readily removed, whilst with another drug its effect is got rid of with much more difficulty, whilst in the case of a third its influence cannot be got rid of at all. The experiments were performed with Roy's tonometer, by means of which an artificial circulation can be maintained through the ventricle by a syphon action. In each experiment I employed 100 cc. of blood mixture, made by dissolving bullock's blood in saline solution. I took tracings first of the heart's contractions with this mixture, and then added to the whole circulating mass dose after dose of the substance experimented with, until the ventricle lost its contractility and failed to respond to a strong induction shock; then to the whole mass of the blood mixture I added an equal quantity of saline or an equal quantity of blood mixture, so that the same quantity of poison circulated through the ventricle, but in a much diluted form. In case neither dilution restored contractility, I replaced the poisoned blood with fresh unpoisoned blood mixture. These experiments show that the action at least of many poisons depends on the degree of their concentration. A given quantity administered in a concentrated form will act more energetically than a larger quantity in a more dilute form. For example, experimenting with the frog's ventricle, on adding a potash salt to the circulating fluid, the contractility grows less and less, and at last disappears; so that a strong induction shock fails to contract the ventricle. When, however, the circulating fluid is diluted with an equal quantity of saline solution, good contractility speedily returns. In this experiment the contractility returns although the ventricle receives the same quantity of potash only in a more dilute form. Indeed, in the case of the inorganic salts in the blood, this arrangement must prevail, otherwise the functions of the body would soon be all arrested.

In my experiments with the frog's heart, I find that with some salts dilution with saline solution is adequate to remove the depressing effect. With other salts dilution with blood mixture is necessary; and in some cases the poisoned blood mixture must be replaced with unpoisoned blood, producing thus, of course, a very large dilution. For instance, simple dilution with an equal amount of saline solution will restore good contractions in a

ventricle arrested by potassium, ammonium, and sodium salts, extract of opium, ethylic alcohol, extract of muscaria, and liquid extract of jaborandi. Very free dilution—i.e., threefold dilution—with blood mixture removed the effects of veratria; but the substitution of fresh blood mixture for the poisoned blood of course made the experiment far more effective. The substitution of fresh blood for poisoned blood mixture restored good contractions to a ventricle arrested by arseniate of soda. On the other hand, the substitution of unpoisoned blood for poisoned blood mixture failed to restore contractions to a ventricle arrested by aconitia, arseniate of soda, chloral hydrate, and strophanthin. I have thoroughly investigated the effect of dilution on the action of potassium chloride, and now give in detail my experiments.

On April 13th, 1882, I added in one dose 2 cc. of 10 per cent. solution of chloride of potassium, a larger dose than is required to arrest the ventricle, for previous experiments show that on an average 1.5 cc. will suspend contractility (both spontaneous and excited). In about fifteen seconds after the addition of this dose the ventricle stopped beating, and strong faradaic shocks failed to induce any contraction. This dose produced some spasm, which lasted about ten minutes, gradually growing less, and finally disappearing. After an interval of forty-eight minutes, during which time the ventricle did not beat spontaneously nor respond to very strong induction shocks, I added to the circulating blood 100 cc. of saline. In a little over four minutes induction shocks with the secondary coil at 0 excited weak contractions, which grew gradually stronger, and could then be induced by a weaker excitation. Ten minutes after the first addition of saline I added another 50 cc.; fifteen minutes after the first addition the ventricle beat good spontaneous contractions, almost as good and quite as frequent as before the operation. However, on applying continued faradization to the ventricle, the secondary coil standing at 2, I arrested the spontaneous contractions and brought the ventricle to a standstill, but on discontinuing the faradization it at once resumed contraction. Although, then, the ventricle had to a great extent recovered itself, and gave good and frequent spontaneous beat, it was still so far under the influence of the potash salt that strong continued faradization, instead of exciting tetanus as in an unpoisoned heart, arrested the spontaneous beats. I then added another 100 cc. of saline, and the contractions continued as strong and as frequent as before, but still continued faradization arrested the ventricle. I then substituted some fresh blood mixture for the previous circulating fluid, and the contractions became more frequent and not quite so strong, but at this point continued faradization produced imperfect tetanus.

On April 12th I added 3 cc. of 10 per cent. solution. This arrested contractility, notwithstanding the application of a strong induction shock, in about twenty seconds. This large dose induced more marked and more persistent spasm than in the previous experiment. In thirty-three minutes I added 100 cc. of saline solution, and in four minutes a similar quantity. In ninety seconds after the last dose contractions returned, and became good, but, as happened in the last experiment, continued faradization arrested them. On another occasion, after suspending contractility by the addition of 1.5 cc. of the chloride of potassium solution, I allowed an hour to elapse before adding 100 cc. of saline. In a few seconds good and frequent spontaneous contractions set in, though less strong than before the addition by the salt. At another time, after the addition of 1.3 cc. of potassium solution the ventricles remained for

twenty-four minutes incapable of contraction, when I added 100 cc. of saline, and in a few seconds good spontaneous contractions ensued, contractions as good and as frequent as before the experiment. I then adopted another testing method. I employed the usual 100 cc. of the blood mixture, but diluted it with 100 cc. of saline, and then from time to time in small quantities added a 1 per cent. potassium chloride solution till strong induction shocks could no longer be produced. In two experiments I found that 37 cc. and 36 cc. were required to arrest the ventricles. I used double the amount required, when only half the quantity (100 cc.) of circulating blood is used. On another occasion I employed 100 cc. of blood mixture with 200 of saline; 52 cc. of the 1 per cent. solution were needed to arrest contractility, or rather more than three times the quantity required to arrest contractility when only 100 cc. of circulating blood is employed.

Next tried a third method. By the addition of 1.5 cc. of 10 per cent. solution in successive doses I arrested the contractility, and then added 100 cc. of saline; good spontaneous contractions ensued. I then again arrested the contractility by the further addition of the potassium chloride solution and in the addition of another 100 cc. of saline good spontaneous contractions returned a second time. I then a third time arrested contractility, adding more potassium solution, so that in all 5 cc. were added (more than three times the quantity necessary to arrest the ventricle when added to only 100 cc. of circulating blood). I then added another 100 cc. of saline, and again good spontaneous contractions returned, which became arrested on the application of continuous faradization. That the arrest of contractility is due to the concentration of the dose, and not to the amount sent by the ventricle, is shown by the rapidity of the loss of contractility. Thus, on adding to the circulating fluid a single large dose of potassium chloride, enough to arrest or greatly weaken the ventricle, in a few seconds, even before many drachms can have passed through the ventricle, its contractility is suspended, and cannot be re-excited even by a strong induction shock.

The effect of a strong percentage dose is also shown in the following experiment, performed by Dr. Sainsbury. He injected a small dose of potassium solution into the afferent tube leading to the ventricle. It thus was very little diluted with blood, and reaching the ventricle in a concentrated condition, arrested it. The blood, however, following, diluted the potash solution in the ventricle, and contractions soon returned.

It is interesting to note that potassium, sodium, and ammonium salts will suspend for an hour or longer not only spontaneous action, but contractility, so that a strong induction shock will not excite a contraction, and yet on dilution good spontaneous contractions recur. The action of these salts on the heart may be compared to the action of anæsthetics on the central nervous system.

It is probable that substances which affect the heart, according to the degree of concentration, act in the same way on other tissues. If so, then it is obvious that in cases of poisoning by any of these salts, we should give the patient abundant supply of fluids to dilute the poison, and to act on the kidneys and skin, and thus help to carry off the poison from the system. It is feasible, too, that in certain cases this dilution of the blood may be aided by bleeding the patient, and, if necessary, by both bleeding and transfusion, a mode of treating which has been successfully adopted in poisoning by phosphorus, etc. This effect of dilution is, I am told, well known to some who, on

getting drunk, speedily sober themselves by drinking very freely of water.

By the light of these experiments we can readily explain Aubert and Dehn's observations. They arrested the heart of a dog by injecting a solution of potassium chloride into the jugular vein, and then restored contractions by connecting the crural artery of another dog with the jugular vein of the poisoned dog. Here the transfused blood of the unpoisoned dog diluted the blood of the poisoned animal, and so obviated the effect of potash to arrest the heart. I find that cane sugar weakens the contractility of the ventricle, and in large doses will even suspend contractility; but the dilution of the circulating fluid with saline solution restores good spontaneous contractions. In this fact we seem to have an explanation of the use in storing up glycogen in the liver; for if after every meal the sugar were at once poured into the general circulation, the excess of sugar would depress the functions of the body.

The foregoing observations seem to me suggestive of rules for guidance in prescribing medicines. For instance, when giving powerful drugs, like curare, conia, or physostigma, in toxic doses to produce paresis, as in chorea, tetanus, and other paroxysmal diseases, it is better to give small and frequent doses, rather than large and less frequent doses. Should the stomach be empty at the time large and infrequent doses are given they might be absorbed quickly, and produce more marked effects than we might desire. I have seen this occur, I think, in the case of conia. Again, in administering alkalies, etc., to render the urine neutral, or in epilepsy, especially in the case of potassium salts, it is better to give smaller doses frequently, and so prevent the percentage of potash in the blood becoming large enough to depress the heart.

In cases of poisoning we can dilute the blood by drinking fluid, or if that method is impossible, the fluid may be injected into the rectum, or even into a vein or the abdominal cavity. The fluid to be employed should be of such a character that it will not destroy the red corpuscles of the blood, and be the best adapted to sustain the functions of the tissues. Certain experiments recorded in the *Journal of Physiology*, vol. iv., No. 1, show that the heart's contractility can be sustained only by an alkaline fluid containing lime and potash salts—namely, potassium chloride 1 part in 10,000 to 15,000, chloride of calcium 1 part in 5,000 to 10,000. Any other combination of the salts of the blood without lime is incapable of sustaining the heart's contractility. It is fair, I think, to conclude that the salts needful to sustain the heart's contractility are likewise necessary to sustain the contractility of the skeletal muscles, and possibly may be likewise indispensable to the performance of nervous function. I would then suggest as a useful fluid 100 cc. of a saline solution containing .75 per cent. of common salt, with potassium chloride 1 cc. of 1 per cent. solution, sodium bicarbonate 5 cc. of 1 per cent. solution, and calcium chloride 2.5 cc. of 1 per cent. solution. In a recent number of *THE LANCET*, Mr. C. E. Jennings recommends as "an almost perfect substitute for blood transfusion" the following solution: Water 20 ounces, sodium chloride 50 grains, potassium chloride 3 grains, sulphate of soda 2.5 grains, carbonate of soda 2.5 grains, phosphate of soda 2 grains, containing two drachms of absolute alcohol. By means of Roy's tonometer I have tested the action of this solution on the ventricle of the frog's heart, both with and without alcohol, and in the strength recommended, and in double that strength, and find that the ventricle fed with this solution rapidly grows weak and soon loses its

contractility, so that it neither beats spontaneously, nor will it respond to a strong inductive shock.

Now I find that on adding 2 to 2.5 cc. of 1 per cent. solution of calcium chloride, spontaneous contractions soon recommence and become good. I would advise, therefore, the addition of calcium chloride to Mr. Jennings' solution; but as his solution on the addition of calcium chloride becomes cloudy from the formation of calcium carbonate, it is better to use sodium bicarbonate instead of sodium carbonate. In a case of poisoning, after washing out the stomach the patient should drink very largely of one or other of these fluids. If he is insensible, it may be introduced by a tube; but as absorption from the stomach may prove too slow, then, I think, in certain cases it may be warrantable to inject the fluid at a temperature of 100° into the abdominal cavity or directly into a vein. If in a place where no defibrinated blood can be obtained, or if in insufficient quantity, the free ingestion of this fluid will of course dilute the poison in the blood, and get rid of some of it through the kidneys and skin. Whilst we thereby dilute and diminish the poison circulating in the blood, we have got another resource in venesection, which will not only run off some of the poison with the blood, but will also assist the absorption of the saline solution.

ST. THOMAS'S HOSPITAL.

ANEURISM OF THE FEMORAL ARTERY IN HUNTER'S CANAL; DIGITAL COMPRESSION FOR TWENTY-FOUR HOURS; CURE.

(Under the care of Sir W. MAC CORMAC.)

For the following notes we are indebted to Mr. White, house-surgeon.

Charles C—, aged twenty-nine, a china-packer, was admitted on December 5th, 1882. The patient was a well-made, broad-shouldered man, of dark complexion, in height 6 ft. 1 in. He had lived an active life. From 1870 to 1875 he was a private in the Life Guards; in 1875 he was engaged in the Canadian police, and in 1879 he returned to this country, and till within the last year he had followed the occupation of a packer. In 1874 he had a chancre, which was followed in a short time by a rash over his body, sore-throat, and pains in the shins; according to patient he had been treated, but to what extent was not ascertainable. His previous health had been good, and he had not had rheumatism. It was about a year before admission that his health gave way, and he was advised on account of heart disease to rest in bed, where he remained up to admission. While lying in bed, about a month before entering the hospital, he first noticed a pulsating swelling of small size in the lower part of the left thigh.

When examined on admission, the patient was

(34)

found to have a fusiform swelling, painful to the touch, about the size of a large lemon, and measuring three inches from above downwards. Distensible pulsation was well marked. The tumour occupied the lower third of Hunter's canal; it was fairly movable, and upon compression of the femoral artery all pulsation ceased, and the sac partially emptied. There was a well-marked bruit conducted down to the calf. The leg was warm, and the pulsation of the posterior tibial artery could be felt. The arteries were thickened; pulse 89, collapsing. The heart was enlarged, the apex beat being two inches below and two inches external to the nipple; there was a thrill at the apex; heart-sound to the right of sternum, a loud double murmur was heard. There were no symptoms of aneurism in the chest; urine normal; temperature 100°.

Dec. 12th: The patient having rested in bed for a few days upon low diet, his pulse fell to about 80 and his temperature to the normal. Digital compression of the femoral was maintained by relays of students selected from the hospital dressers, each to go on for a ten-minutes' spell, his successor to get his fingers on the artery, and to compress each time at a different place before the other relaxed his pressure. Compression was commenced at 8.30 A.M. At midnight the sac was nearly filled with clot, and the pulsation considerably diminished. There was still some pulsation to be felt in the posterior tibial artery. The compression was continued.—13th, 10 A.M.: A little more than twenty-four hours after the treatment was commenced the tumour was quite solid; no pulsation could be discovered in the sac nor in the tibial artery; the limb was warm. Compression was discontinued. The patient felt well. Several anastomosing vessels visibly pulsated around the knee.—16th: The patient well; limb warm; pulse 80; temperature 98°. No return of pulsation in the tumour, which is much more solid.—21st: Pulsation could not for the first time be felt in the posterior tibial artery; no return in the sac; pulse 85; temperature 98.6°.

From this time until Jan. 5th, 1883, when the patient got up for the first time, all went well, and he was now up and about the ward, completely relieved of his clot.

The sac contracted to one-third its former size, became quite hard, and gave the patient no inconvenience. He has since left the hospital convalescent. The absence of any exciting cause is an interesting feature in this case. It affords, too, another instance of the satisfactory results obtainable by carefully applied digital pressure, even under, as in his case, circumstances not otherwise favorable.

CASE OF TROPICAL ABSCESS OF LIVER; PARACENTESIS; SUBPERIOSTEAL REMOVAL OF PORTION OF NINTH RIB; FREE OPENING; RECOVERY.

(Under the care of Mr. GEORGE GULLIVER, M.B.)

T. C—, aged twenty-five, was admitted to Arthur ward on Aug. 24th, 1882. The family history presented no facts of importance. Thirteen years ago patient had "gastric fever." In 1875 he enlisted in the army. In 1878 he went with his regiment to Bengal, and that year he had an attack of pleurisy in the left side. He remained in Bengal till 1881, and during his stay there had several attacks of fever and ague, till eventually, at the end of the year 1881, at the expiration of his period of service, he was invalided from Netley Hospital for ague, which rendered him unfit to join the reserve, as he would otherwise have done. He never suffered from diarrhoea or dysentery; he was a temperate, well-conducted young man, and had

two good-conduct badges. A month or two after leaving Netley he was able to take employment as an out-door laborer.

On July 20th, 1882, rather more than a month before his admission, whilst working in the rain, he was attacked with pain in the right shoulder, vomiting, chilliness, and a slight hacking cough, and was obliged to leave off work and go home. These symptoms continued, and in addition his appetite failed; he lost flesh much, his bowels were from time to time relaxed, and he occasionally coughed up small clots of blood. He presented himself as an out-patient on August 24th, and entered the hospital on being advised to do so.

His state on admission was as follows:—A tall, muscular, but considerably emaciated man, complaining of the symptoms just enumerated; complexion very sallow; conjunctivæ slightly jaundiced. Was perspiring a good deal; temperature 102°; heart normal; pulse 80, soft, regular. On the right side of chest there was dullness in front from the fifth rib downwards, and posteriorly the lower quarter of the chest was dull. Over the dull area the breathing and voice sounds were diminished, except at the extreme upper margin of the area where the breathing was tubular and the voice bronchophonic. The left lung was normal; the liver extended two and a half inches below the ribs in the right nipple-line, and the edge was somewhat tender on palpation. The spleen appeared normal, tongue moist, coated with white fur, urine, sp. gr. 1011, no albumen. There was nowhere any indication of an abscess being about to come to the surface. The diagnosis rested between a fluid accumulation in the pleura, depressing and causing secondary congestion of the liver, a suppurating hydatid in the liver, or possibly between the liver and diaphragm, and, lastly, an idiopathic hepatic abscess. He remained in the hospital for nearly three weeks without any active steps being taken for his relief, partly on account of the uncertainty of the diagnosis, and partly because his condition did not appear to call for immediate active treatment. During this period the symptoms remained much the same, that of which he complained the most being the pain in the right shoulder. The liver descended lower till it reached nearly to the umbilicus, and it was tense and elastic to the touch, but nowhere fluctuating. The upper margin of the dullness in the back at the same time ascended till the lower third of the back was involved. His temperature varied from being occasionally normal in the morning to 103° in the evening. With a view to clearing up the diagnosis on three occasions, a puncture was made with a morphia syringe into the dull area of the back. On the first two occasions nothing but a little blood came away, but on the third attempt a few drops of brownish-colored serum were withdrawn. Though the color of this was certainly suggestive of hepatic origin, it was not opaque enough to make it certain that it was part of the contents of an hepatic abscess, at least as ordinarily seen. On the afternoon of September 18th, he had a transitory but somewhat alarming attack of dyspnoea, fearing the recurrence of which Mr. Gulliver determined to take active steps for his relief, and accordingly asked his colleague, Mr. Pitts, who was then resident assistant-surgeon, to see the patient. This he did on the evening of the same day. He also failed to detect any appearance of an abscess forming or fluctuation, but on account of the elastic feel of the liver in the epigastrium, being somewhat suggestive of a deep-seated abscess in that situation, he first of all inserted the trocar of the aspirator into the liver at that point, but without result. The trocar was then in-

serted for some distance at a point between the eighth and ninth ribs and posterior to the mid-axillary line. The result was the withdrawal of a quantity of thick chocolate-colored matter, such as in the most typical cases comes from an abscess of the liver. In all four pints two ounces came away, and more would have come with ease, but it was thought that sufficient had been done for purposes of diagnosis, and to ensure the safety of the patient against an attack of dyspnoea, and that, moreover, aspiration could be merely palliative and preliminary to making a free opening for the escape of the pus. After the paracentesis the patient had a severe attack of pain in the lower part of the abdomen, which, however, quickly yielded to morphia. The next day there was no pain, and the edge of the liver reached only two inches below the margin of the ribs. There was, however, no diminution of the pyrexia, the temperature being 103° on the afternoon of the day succeeding the operation, and 101° and 102° on the two succeeding days. At the same time the pus began rapidly to reaccumulate, as was indicated by the rapid depression of the edge of the liver, till on the fourth day after the tapping the patient's condition seemed to be much the same as before that operation, his temperature in the morning being 102°. It was consequently thought advisable to delay no longer making a free incision.

On Sept. 16th the patient was placed under ether and Mr. Pitts made an incision just anteriorly to the angle of the ninth rib, and removed subperiosteally a portion of it, about an inch and a half in length. On cutting into the pleura beneath this there escaped some ounces of thin brownish serum of about the color and consistence of thin beef-tea, and similar to that which had formerly been removed by the hypodermic syringe. A free incision was then made into the liver through the diaphragm, and about three pints of pus of the same kind as had been removed by the aspirator came away through the opening. Two large drainage-tubes were then inserted, being well packed round with gauze to prevent the escape of matter into the pleural cavity. No vessel required ligature. The operation was conducted with the strictest antiseptic precautions. The cavity was not syringed out.

There remains little to record except the almost uninterrupted convalescence of the patient. On the evening of the day of operation the temperature was subnormal, and it did not rise above normal till the twenty-sixth day after the operation. The wound was dressed about every third day under the carbolic spray, the cavity being syringed out with a solution of oil of eucalyptus, the discharge never exceeding two or three ounces. The antiseptic dressings were discontinued on Oct. 11th, and a dressing of carbolic oil and iodoform gauze substituted. The drainage-tubes, which had been shortened from time to time, were finally removed on Nov. 21st, and a few days afterwards he was allowed to get up, whilst waiting his turn of admission to a convalescent home. His convalescence was interrupted by a rise of temperature on Oct. 11th, due to a slight attack of pneumonia, at the base of the right lung in the neighborhood of the abscess cavity, the signs being cough, with blood-stained expectoration, dullness, with crepitation and tubular breathing. The temperature reached 103·8°. For four or five days it remained more or less elevated, but never to such an extent as to cause any serious alarm. For three days after the operation he took milk and beef-tea only, after that he had milk diet and eggs, and about ten days after the operation he had chicken. His appetite soon improved, and, as soon as he cared for it, he had ordinary diet. In addition he had

about three glasses of wine every day. The only medicine which he took was a mixture of a little hydrochloric acid and tincture of nuxvomica in water, sweetened with syrup of oranges.

On December 6th the patient went to a convalescent home. On his return, on January 3rd, 1883, he presented himself in the out-patient room in all respects perfectly well. He had become very stout. The wound had healed perfectly, no fistula remaining; and it was not possible to detect that any portion of a rib had been removed. His chest was perfectly normal, with the exception of some slight impairment of resonance at the right base, which was only what one would expect from thickening and adhesions of the pleura at that spot. The liver could not be felt below the ribs.

Remarks by Mr. GULLIVER.—The case is interesting from the doubts which were at first entertained as to its nature, and which were only removed by aspiration; the more so as it was shown at the operation that some ounces of fluid did exist in the pleura, though without doubt due to inflammation secondary to the hepatic abscess. The unusually large size of the abscess necessitated a very free and dependent opening, which called for the removal of a piece of rib. No vessel required to be tied during the operation, and no bad consequences ensued on it. The abscess was reached through the pleural cavity and diaphragm without harm resulting, the precaution having been taken of packing the drainage-tubes round with gauze. The rapid reaccumulation of pus after aspiration tended to demonstrate the futility of that operation for anything more than temporary relief. Lastly, I should say that the complete recovery of the patients was entirely due to the skilful manner in which the operation was performed, and the subsequent treatment carried out by my colleague, Mr. Pitts. I am indebted to Dr. Harley, whose work I was doing at the time of the patient's admission, for permission to publish the case.

RADCLIFFE INFIRMARY, OXFORD.

CASE OF EXTRA-UTERINE PREGNATION FOLLOWED BY THE
EXPULSION OF FETAL BONES THROUGH THE BLADDER:
PERMANENT UTERO-VESICAL FISTULA; REMARKS.

(Under the care of Mr. H. P. SYMONDS.

For the following notes we are indebted to Mr. J. E. Hine, M.B., late resident medical officer.

Mrs. A.—, aged forty, was admitted in August, 1880, with symptoms of stone in the bladder and with an extreme degree of cystitis. Her history was as follows: Menstruation began when she was thirteen, and has been regular till recently. She married at the age of sixteen. The first child was born alive ten months afterwards, at full time. This was followed at intervals of about two years by a miscarriage of twins at the fourth month; another miscarriage at the third month; then a child at full time, still living. Then another child, also living, and then another miscarriage. Twelve years ago, when pregnant four months, she had a fall which caused abortion, and was followed by inflammation of the womb. She says that a fully formed foetus came away, together with something else which the nurse told her was "like a piece of flesh with a bone stuck in it." She had severe flooding and great pain in the abdomen both before and after the miscarriage, and was ill for three months. Ever since this illness she has menstruated through the bladder, the periods being regular and the flow normal in amount. For two years after the illness she had a constant discharge

of matter from the bladder, and on several occasions for nine months from the time of the miscarriage she passed fetal bones. One of these, she says, resembled a blade bone; others were long bones. The discharge of pus gradually ceased, and she was able for several years to get about as usual, her only trouble being the menstruation through the bladder, which often gave her pain through clots blocking up the urethra and causing retention. At the end of 1879 she had one day a sudden pain in the abdomen and stoppage of urine, followed shortly afterwards by the passage of two small stones, the size of peas, rough on the surface and hard. She went on quite well after this till June, 1880, when she had a repetition of the same symptoms, and passed, together with bloody urine, a bone about an inch long, which crumbled when she took it up. At the same time the discharge of pus recommenced. She came into the infirmary in August. On the 13th lithotripsy was performed, and a few drachms of phosphatic material without any nucleus were removed. She was relieved by the operation. Two days later a sound was about to be passed into the bladder, when there was found emerging from the urethra a foreign body which proved to be a fetal scapula of about the fourth month. The urethra was dilated and the bladder explored by the finger. A cavity was felt at the base of the bladder, but outside its walls, containing fragments. From this more fetal bones were removed, but owing to considerable hæmorrhage the whole were not taken away. For a few days after more fetal remains were passed with the urine, and in ten days the operation was repeated with similar result as before. After a third sitting no more fragments could be felt and no more were passed. From time to time after the operation the patient had attacks of pain, due apparently to local inflammation. In October she was discharged, feeling quite well. By vaginal examination the uterus was found not very movable. In front of it a thick mass was felt between it and the bladder. The sound passed one inch and a half through the os uteri, and could be felt when the finger was in the bladder to be in the cavity at the base, in which the bones were. Since she left the infirmary, more than two years ago, she has had no more trouble. The sound now does not enter the bladder, the uterus is more movable, and the thickened mass has disappeared. She still menstruates through the bladder.

Remarks by Mr. SYMONDS.—From this history it will be seen that when in 1870 the patient had miscarriage at the fourth month she was delivered of a foetus; yet from the date of this illness, which was accompanied with "inflammation of the womb," she passed fetal bones from the bladder. This seems to indicate that there was a twin pregnancy, one foetus being in the uterus, the other extra-uterine or in the wall of the uterus. The latter, ruptured by accident, inflamed and suppurated, eventually opening into the bladder, and leaving a fistulous communication between it and the uterus, by means of which menstruation takes place. The cavity went on suppurating till 1872, fetal bones being passed from time to time. Then there was a long interval, and all the symptoms, except the menstrual, subsided till the end of 1879. All this time from some cause the suppuration began again, a few more bones coming away, till she entered the infirmary, and the cavity was cleaned out, and the source of the irritation thus removed. From the fact that the sound could be passed through the os into the bladder, but that the menstrual flow passed from the bladder only, it seems that the upper part of the uterus was cut off from the lower part by some inflammatory ad-

hesions following the original disease. As this case is one of considerable rarity, I have thought it well to give the details at length.

ST. ANDREW'S HOSPITAL FOR MENTAL DISEASES, NORTHAMPTON.

A CASE OF SUICIDE BY OXALIC ACID; NECROPSY; REMARKS.

(Under the care of Mr. J. BAYLEY, Medical Superintendent.)

For the report of the following case we are indebted to Mr. E. F. Cooper, assistant medical officer.

W. H. S—, aged forty-seven, paper manufacturer, was admitted on Dec. 21st, 1882, suffering from (1) melancholia and (2) oxalic acid poisoning. From the statement of the friend who accompanied him, and from information subsequently received, it appeared that the patient had, a week or ten days previously, attempted to destroy himself by means of laudanum, and that on the day prior to his admission he had obtained at a neighboring pharmacy two drachms of oxalic acid, with which he immediately proceeded to a refreshment-house and there swallowed in coffee. The chemist who supplied the poison was quickly on the spot and induced vomiting, the vomited matter, as he stated, causing blackening of the floor; carbonate of magnesia and demulcents were also administered. From the time of his admission the patient was depressed, and complained of pain in his back and abdomen, and was sick at intervals, until on Christmas evening respiration became very hurried and he died in the night, conscious to the last. The treatment consisted in the administration of milk, lime-water, and carbonate of magnesia, while, after the first day or two, beef-tea and custard-pudding were given in addition, together with three ounces of brandy per diem.

At the post-mortem examination, made on the requisition of the coroner by a gentleman unconnected with the hospital, the stomach was found to be intensely congested over a portion of its inner surface, and contained about a third of a pint of thick blood-stained fluid; the lower end of the œsophagus was in the same inflamed state; there was double pneumonia, with adhesions of the left pleura, and effusion into the right one.

Remarks.—The comparative smallness of the quantity of the poison taken is an interesting feature in the case. One drachm is recorded as having caused the death of a boy, aged sixteen, with which exception this is the smallest fatal dose of which I have found mention.

GUY'S HOSPITAL.

HÆMATOCELE OF TUNICA VAGINALIS, FOLLOWING TAPPING OF HYDROCELE; INCISION; RECOVERY.

(Under the care of Mr. BRYANT.)

For the following notes we are indebted to Mr. Kendall.

Wm. S—, aged fifty-eight, was admitted into Job ward on May 24th, 1881. In April, 1878, he was in Lazarus ward, under Mr. Durham. He had suffered from gonorrhœa twenty-three years before, and small-pox. About this time he was kicked in the scrotum; though he had not much pain or swelling, he wore a suspender for some time. On April 6th, 1878, two days before his admission under Mr. Durham, he was struck in the scrotum by a crane, and when admitted the left side of the scrotum was much distended, painful on pressure,

and the veins were apparently much congested. The scrotum was tapped, and a quantity of yellow serous fluid escaped. The scrotum was strapped, and the patient went out. Six weeks later the scrotum swelled again, and was tapped. For two years he had no more trouble.

On May 23rd, 1881, he presented himself at the hospital with his scrotum distended. It was tapped, and on drawing off the fluid the swelling returned again, and blood spurted from the wound on withdrawing the trocar. There was ecchymosis of the left side of the scrotum. The penis was very œdematous; the swelling on the left side was very tense, but extended up to the external abdominal ring; the scrotal tissue could be pinched up between the fingers. The refrigerator was applied.

On June 2nd the swelling had increased and become more tense at the upper and outer part of the scrotum, on the left side, but the lower part of the scrotum remained in the same condition as previously. The patient complained of pain in the left cord. Next day the tunica vaginalis was laid freely open, and a large quantity of recent blood-clot removed. The testis was freely exposed. The tunica vaginalis was thickened, and its inner surface irregular. There was no bleeding of importance. The surface was thoroughly cleansed with sponges and iodine and water. The patient had injection of morphia in the evening, but he did not sleep; and on the following morning he complained of pain along the back of the scrotum and in the hypogastric region and tenderness of the testicle. Temperature and pulse normal; appetite good. On the 6th the urine when examined showed a sediment consisting of the triple phosphates, with pus and epithelium cells; specific gravity 1030. On the 11th sloughs came out of the wound, and on July 12th the cavity had entirely closed, nothing remaining but a small fissure.

MANCHESTER ROYAL INFIRMARY.

A CASE OF PERFORATING ULCERS ON BOTH FEET.

(Under the care of Mr. FREDERICK HEATH.)

For the following notes we are indebted to Mr. John Priestley, house-surgeon.

The published cases of perforating ulcer of the foot in which a complete examination has been made of the microscopic appearances of the nervous lesions are not as yet by any means common.

C. W—, aged forty-two years, married, had followed the vocation of porter for several years. When he was twenty-two years of age he was in the army, and contracted syphilis. Unfortunately the notes of the case when the patient first came under observation, and before he passed into Mr. Heath's care, are not so complete as could be wished, although the general course of the malady is obvious enough. In 1877 the patient suffered from a sinus in the sole of the left foot, the antecedent conditions of which are not recorded in the notes. Through this sinus pieces of dead bone escaped. About the same time a hard and very painful swelling began to be noticed in the middle of the sole of the same (the left) foot. In 1878 there occurs in the hospital note-book the observation of an ulcer in the sole of the right foot, situated over the fourth toe, for the healing of which the toe was amputated. In July, 1881, as the wound had not closed, and as the third toe of the right foot seemed to be involved, this toe also was amputated. The patient was thereupon sent to the Cheadle Convalescent Hospital for eleven weeks.

November, 1881.—The wound still remaining open, and the first and second toes having fallen

under the disease, Mr. Heath amputated the foot by Syme's operation. It had been remarked on several occasions that this foot sweated freely and often had a fetid odor. The nerves in the stump and in the amputated foot were much thickened, and presented the microscopic appearance to be afterwards described. In February, 1882, the swelling under the sole of the left foot was lanced.

In March, 1882, the patient was readmitted from Cheadle with an ulcer on the inner side of the Syme's stump, and a round ulcer, as large as half a crown under the sole of the left foot, lying over the bases of the third and fourth metatarsal bones. The ulcer (or rather the still unhealed portion of the cicatrix) of the Syme's stump disappeared with remarkable slowness; but it did finally become healed, more or less soundly, while the patient was in bed. Meanwhile the round ulcer on the left sole grew in depth and breadth. Its edges were heaped-up, crater-like, horny, and somewhat undermined. The base was even and filled with regular granulations. The whole foot was flat or even arched downwards, owing to the prominence of the region occupied by the base of the first metatarsal bone, the internal cuneiform and the scaphoid bones. The skin of the sole round about the ulcer was hyper-sensitive, as was also the skin of the dorsum of the foot and of the leg; there was not at any time anæsthesia of the leg or foot, and, according to the patient's statement, there had never been any free or fetid sweating in this limb; a statement which was corroborated by our observation of the case during the summer of 1882. Reflex action from the sole was remarkably increased. There was no retardation of sensation, and the patient could discriminate well between a pin-point and a pin-head lightly applied to the skin. The tendon-reflex at the knees was very active; ankle-clonus was marked; the cremasteric reflex was present; and the abdominal and interscapular superficial reflexes were also lively. The pupillary reflex to light and accommodation was normal. It was decided to amputate this leg high up above the thickened nerve-trunks, as the healing of the opposite foot after removal had been so slow and insecure. Amputation above the middle of the leg by a long posterior flap was therefore performed, and with the best results. The posterior tibial nerves from both amputated limbs were examined, as well as a portion of the posterior tibial nerve from the end of the stump in the second (leg) operation. This last named piece of nerve was apparently quite normal, and served as the standard with which to compare the thickened portions of nerve from the neighborhood of the ulcers. The thickened nerve in sections, stained with logwood or with carmine, exhibits a great increase of the connective tissue, especially of the peri and epi-neurium. The lymph spaces surrounding each nerve bundle in the trunk seem much expanded. The nerve fibres in the bundles are sparsely scattered, being fewer in a given area than in sections of the same nerve in the healthy mid-portion of the leg, and the intervening connecting endo-neural substance seems to be present in greater quantity than usual. In short, the microscopical appearances resemble very closely those figured in the illustrations to the article by Messrs. Savory and Butlin in the *Medical and Chirurgical Transactions*, Vol. lxii., 1879, p. 373.

The chief points in which the above case differs from some cases previously recorded are included in the clinical history—viz., (1) there was no anæsthesia of the affected limbs, but, on the contrary, in the case of the left leg at least hyper-sensitiveness; (2) there was no profuse or fetid sweating in the left leg and foot, although this seems occasionally to have been observed in the right; and (3) there

was no diminution of tendon reflexes. All these symptoms have been claimed by different observers as characteristic of perforating ulcer. The patient was seen during the first week of the present year (1883), and both stumps appeared soundly healed. He has already begun to wear a socket for the Syme's stump.

INFIRMARY FOR CHILDREN, LIVERPOOL.

CASE OF INTUSSUSCEPTION; OPERATION; DEATH.

(Under the care of Dr. POLLARD.)

For the following notes we are indebted to Mr. C. Couper Cripps, M.B., assistant house-surgeon.

Mary T—, aged three, was admitted on Dec. 12th, 1882, with a history of supposed injury to the abdomen about ten weeks previous, constant pain in this region since, gradual loss of flesh, occasional vomiting for about the last three weeks, and during the three days before admission passing nothing but clear muco-gelatinous matter from the bowels, which had been moved only with the aid of medicine.

On being presented at the hospital the patient was emaciated and weak and looked very ill. Examination under chloroform disclosed the existence of an elongated, firm, and somewhat lobulated tumour, apparently fixed, extending from the left iliac fossa below the umbilicus almost to the right side. On exploration with the needle of a hypodermic syringe nothing was obtained.

On the 14th a mass of prolapsed intestine could be felt with the finger in the rectum reaching to within two inches of the anus; it was firm, globular, and presented an opening (the continuation of the intestinal canal) into which the finger could be easily inserted. The abdomen, although tender, was not distended. Injection with inversion and gentle manipulation failed to effect reduction, but the bowels were afterwards moved twice, the motions being small and feculent.

The patient was kept under the influence of opium. Injection having again been ineffectually tried, it was decided on the 16th to perform abdominal section, the abdomen being now somewhat distended and bloody mucus being passed at frequent intervals with much tenesmus. Liquid nourishment had been fairly taken since admission, and had only been occasionally ejected, the vomited matters having no fecal odor.

The operation was as follows:—The child being as much as possible protected from cold, the abdomen was opened by an incision in the median line, extending from a point a little above the umbilicus to midway between this and the pubes. Some two feet of small intestine having then been drawn out on to the abdomen and protected with a cloth wrung out of hot water, reduction of a portion of the bowel was effected with difficulty by a process of pulling and kneading. During this proceeding a fissure occurred in the surface of the ensheathing gut by the giving way of the peritoneal coat, and finally this was converted into a rent during further efforts, exposing the invaginated intestine, the last two inches of which were found to be in a gangrenous condition, but with no signs of ulceration or separation. The intussusception having been thus reduced so far as the lower end of the ascending colon, and the adhesions being then found too strong to admit of any further reduction, the invaginated gut, which consisted of the cæcum and its appendix with about three inches of the small intestine, was then removed, the bowels emptied as much as possible of their contents (liquid feces), and the ends of the divided gut united by the continuous suture interrupted at intervals. The wound was then closed with wire sutures.

The child never rallied from the operation, but died three hours afterwards. On reopening the wound, the ends of the divided intestine were found in perfect apposition and the colon and rectum contained liquid feces, which had evidently passed down from above since the operation.

CASE OF RESECTION FOR OSSEOUS ANCHYLOSIS OF THE JAW.

(Under the care of Mr. RHINALLT N. PUGHE.)

Arthur S—, aged three years and nine months, was admitted into the Infirmary on April 26th, 1882, suffering from almost perfect inability to separate the jaws. The following history was obtained from the parents:—Two years before admission he was playing with a handcart, and was struck under the chin by one of the shafts. There was profuse hæmorrhage from the mouth, but no external wound. He was taken at once to a hospital, where he remained for three weeks. The parents were told by the house-surgeon that the jaw was not broken. They do not know what treatment the boy received at the hospital. "His jaw was very stiff, and the stiffness gradually increased," until he became quite unable to separate his teeth.

On admission the boy appeared healthy and well nourished. There was no scar about the face or neck, and no apparent displacement, the incisors coming well together. There seemed to be a little thickening about the left temporo-maxillary articulation, and the depression beneath the zygoma was more indistinct than on the right side; otherwise there was but little appreciable difference between the two sides. Not the slightest lateral and very little vertical movement could be produced even when the boy was completely under the influence of chloroform. The central incisors were wanting, and through the gap left the boy got his food into his mouth.

On April 30th the boy was put under ethidene, and an incision was made on the left side along the zygoma, and another from this in a line with the neck of the jaw posteriorly for a short distance downwards. This flap was turned down and the joint exposed. The neck of the jaw was found much thickened, being quite three-quarters of an inch across antero-posteriorly, and also much thickened from within outwards. The condyle was dislocated forwards and united to the zygoma, all appearance of the joint being lost. There was a superficial groove corresponding to the lower border of the zygoma, otherwise the fusion of the two bones was complete. Some fragments of bone were removed by chisel and gouge from the zygoma and the head of the lower maxillary bone, leaving a gap of about half an inch vertical. In doing this the ramus of the jaw was evidently splintered downwards. The chief difficulty about the operation was the removal of the bony fragments from the deeper part of the wound, as of course the vertical incision was necessarily limited, and care had to be taken not to injure the deeper structures. After the bone had been divided the jaws were separated by a screw-gag, which could now be done with comparative ease, leaving a space of about three-quarters of an inch between the incisors. There was considerable venous hæmorrhage during the operation. The carbolic spray was used the whole time, and the wound dressed antiseptically; slight rise of temperature (100° F.) followed next day, but no pain or other bad symptom. The boy was fed on fluid diet. On the fifth day, the antiseptics having broken down were discontinued, and the wound dressed with a strong lead lotion, which was continued till the wound was healed. Ten days after the operation the

mouth was again opened by the gag, chloroform being given; the jaws could be separated to the extent of about an inch. From this time the gag was used every two or three days, and, at the same time, he was given solid diet.

June 20th.—He can now open his mouth to the extent of about an inch without assistance, but there is no lateral motion whatever. The gag is still used every two or three days; wound quite superficial.

July 12th.—Wound quite healed. The boy has continued much in the same state up to the present date, Dec. 7th.

NATIONAL ORTHOPÆDIC HOSPITAL.

A CASE OF SPINA BIFIDA SUCCESSFULLY TREATED BY INJECTION OF DR. MORTON'S IODO-GLYCERINE SOLUTION.

(Under the care of Mr. E. MUIRHEAD LITTLE.)

MARGARET E—, aged three weeks, was first seen at the hospital last May, with spina bifida in the lumbar region, and strongly-marked congenital talipes varus on both sides. The tumour in the back was some three inches in diameter, and nearly circular; its walls, except close to the periphery, were very thin and transparent, and of a bluish membranous appearance. At the summit, which was raised more than an inch from the surface of the back, was a granulating sore, the size of a halfpenny. The cleft in the bones appeared to extend between the second lumbar and second sacral vertebrae. The child was pale and sickly-looking, with a somewhat large head. The tumour seemed in no way affected when the child cried. The mother stated that the tumour was increasing in size, and that the child moved its lower limbs very little. She was fully alive to the precarious condition of the patient, and readily consented to an operation as affording some chance of cure.

The mother and infant were admitted on June 1st. On the same day the tumour was aspirated and six drachms of clear fluid were withdrawn, and a pad and bandage were lightly applied. The sac was left three-quarters full. On the 3rd the sac had refilled and was again aspirated, and one ounce and a half of fluid was withdrawn. The child was very restless for several days and started at slight excitation. Cried constantly. On the 14th she was in her usual health. The sac was again aspirated and six drachms of fluid were removed. On the 21st the tumour was as large as ever. Half the contents was removed with the aspirator, and twenty minims of Morton's solution were injected. No bad symptoms followed injection. Next day the tumour was redder and more opaque; the sore was smaller. On the 23rd to be out-patient. On the 27th the tumour was much smaller and firmer. The sore was healed. The tumour having ceased to shrink, thirty minims of the solution were injected on the 28th. Collodion was applied on lint.

From this date the tumour rapidly shrank, and in two weeks had disappeared. The skin had much advanced over the surface, but there was still a membranous portion near the centre. A light truss was ordered as a protection, and the treatment of the talipes subsequently proceeded with. The necessary operations have produced no bad symptoms and the child's general health has improved.

Notes by Mr. LITTLE.—In any future case I should be inclined to discard attempts to obtain a cure by simple aspiration, but inject the iodine solution at once. The former plan was advocated by Dr. Morton in his original paper, but I am not aware

whether or no he still follows it. I am indebted to the courtesy of my colleague, Mr. Fisher, for the opportunity of treating this case in the hospital.

METROPOLITAN INFIRMARY, CLEVELAND STREET, W.

THREE CASES OF CARIES OF THE SPINE IN TAILOR-ESSES.

(Under the care of Mr. JOHN HOPKINS, F.R.C.S., and Mr. ROBERT PARRY, M.B.)

DURING the year 1882 three cases of death from caries of the spine having several noteworthy features in common have occurred at this infirmary.

CASE 1.—J. P—, aged sixty-nine, tailoress, was admitted Jan. 2nd, 1882, with paraplegia. She had always had good health, and had never been laid up except from an injury to the hip twenty years previously, occasioned by a fall. Afterwards the limb had become shortened, though it was not believed to be fractured at the time. She had subsequently been able to get about without the support of a stick. A fortnight before admission, while walking along the ward of the workhouse, she suddenly lost the use of both her legs. Previous to that occurrence she had suffered in no other way than from a feeling of dejection and indisposition to work; she then had painful tumefaction of the abdomen and incontinence of urine.

On admission, the lower limbs were powerless, but reflex movements were readily excited by tickling, pinching, or grasping the foot. The seventh dorsal spine was slightly prominent and a little tender on percussion. A triangular area of œdema well defined in outline occupied the loins, the apex of the triangle being situated at about the twelfth dorsal, and the base at the top of the sacrum. Pains occasionally shot down the front of the thighs, more particularly the left, and there were pain and tenderness over the abdomen, which was distended; the bladder was greatly distended and overflowing, and the bowels were confined. The urine withdrawn measured two pints and a half, and on the following day it contained much blood, but this disappeared in three days. The use of the catheter was discontinued after a few days, as incontinence without retention came on. The prominence of the seventh dorsal spine became more marked towards the last, and its distance from the eighth dorsal spine could be altered by raising the patient by the shoulders. A band of hyperæsthesia about the level of the seventh rib was noted on January 20th, and a small superficial bed sore.

The patient died on January 22nd, twenty days after admission and five weeks from the onset of the paralysis.

Necropsy.—The bodies of the seventh and eighth dorsal vertebrae were carious, and had fallen together, and the intervertebral substance had disappeared. The abscess in connection with the diseased bone contained inspissated pus, and formed a pouch on either side of the vertebral bodies larger than a hen's egg, to which the contiguous lung was adherent; there were three other small pouches projecting backwards into the spinal canal; two of these were placed symmetrically between the remaining portion of body of the seventh dorsal, and the posterior common ligament, leaving a furrow between them, at the lower end of which the third pouch projected backwards in the middle line. There was no congestion of the membranes or cord. On passing the finger over the cord a transverse sulcus was felt at the compressed spot. There were abscesses in both kidneys, with

deep congestion, consequent on cystitis and pyelitis. All other internal organs were healthy. There was an old intracapsular fracture of the neck of the left femur.

CASE 2.—Sarah M—, aged thirty-four, tailor-ess, was admitted on December 5th, 1881, with paraplegia. When a child, she had abscesses and necrosis. Six weeks before admission, while walking in the street, her legs gave way under her, and next day her legs were paralyzed. She kept her bed from that time, passed her urine under her, though at one time there was retention.

On admission, the patient was of spare build, thin, and anæmic. Several deep scars showed the seats of old abscesses and necrosis. The right eyeball was useless and shrunken, and part of the floor of the orbit had been removed by necrosis. The legs were somewhat wasted, useless, and flabby, and there was some anæsthesia of both feet. Reflex action was much heightened. There was incontinence of urine, and the bowels were confined. No prominence of the spines was made out on admission, but in January a note was taken that the seventh, eighth, and ninth dorsal spines were prominent, and the left transverse process of the eighth vertebra projected under the skin, the corresponding spine being directed to the right. Bedsores formed very rapidly, a night's rest in one position being enough to give an appearance of threatening gangrene on parts pressed upon. The patient became thoroughly emaciated, and many bedsores formed. She died exhausted, February 2nd, 1882. No post-mortem examination was made in this case.

CASE 3.—Elizabeth D—, aged forty-four, tailor-ess, was admitted March 24th, 1882, with a large, cold abscess over the left thoracic parietes. The woman was a native of North Wales. As a child was delicate, and about puberty acquired a lateral curvature of the spine. Some time after that she fell heavily over an iron railing and hurt her left side. At eighteen years of age she came to London, and soon afterwards took up her late employment, which she pursued for twenty years. For five years before admission she had been feeling ill, but had no pain, and could not say she had anything in particular the matter with her. Four or five months before admission a swelling appeared in the left side; it was free from pain and gradually increased in size.

On admission she felt very depressed but had no pain; she had a slight cough, and on the evening of the 28th her temperature was 100° F. The swelling was situated on the left side, and measured in circumference about as much as a fetal head at term, its centre being placed in the axillary line at about the fifth intercostal space. About a pint of pus was withdrawn by the aspirator, and when the matter had again collected a freer opening was made and a drainage-tube introduced. A few days afterwards a small piece of dead bone was found in the cavity and removed. After the permanent opening was made there was very little discharge, and the wound was subsequently allowed to heal. The matter again collected, at first over the scapula, and disappearing from that spot reappeared in a line with the fifth rib round the chest. An examination of the spine at this time elicited no pain on percussion.

The patient first complained of pain in the right shoulder in the end of April. In October the pain was severe, and extended down the right arm into the ring and little fingers, which felt numb. On Dec. 1st there were pain and stiffness in the neck. Pressure in the vertex could not be borne, and there was a little tenderness on percussion of the seventh cervical spine. An abscess was felt deep under the right trapezius. On Dec. 6th there were

retention of urine and weakness of the lower limbs, and three days later entire loss of power over the right foot, and partial loss over the left occurred. On Dec. 10th the paralysis was complete, and a threatening bed sore appeared over the sacrum, as well as incontinence of urine without retention. On Dec. 13th there were involuntary startings in the left leg and pain in the abdomen, "as if the bowels were being twisted into knots." On the 17th complete paralysis of right hand and weakness of left upper limb. Sensation in the lower limbs fairly good to both touch and warmth throughout. The feet felt numb and subjectively cold. A pain "like liquid fire" shot from the left shoulder across and down the right arm. Next day the tongue was red, marked by deep furrows, and patched with fur. There was a bed sore on the left heel. On Dec. 27th the bed sore over sacrum was the size of a half-crown piece, contained a deep slough. Accumulation of bronchial mucus occurred with dyspnoea, cyanosis, and death.

Necropsy.—There was well-marked lateral curvature to the right in the dorsal region. At the seat of the caries the cervical was flexed upon the dorsal portion of the spine, and rotated to the left. The rotation was due to dislocation forwards of the right side of the seventh cervical vertebra. The outer half of the right transverse process of the first dorsal was broken off, and reunited by firm fibrous bands both to the part from which it had been broken and to the posterior transverse process of the dislocated seventh cervical. The caries had destroyed nearly the whole of the body of the first dorsal, together with the under surface of the seventh cervical. A thin incomplete layer of cartilage loosely attached to the seventh cervical was all that remained of the intervertebral substance. That below the first dorsal had a thin layer of bone upon it, through which the caries had not quite penetrated. The abscess in connection with the diseased bone had come forwards in the neck upon the right side beneath the trapezius and sterno-mastoid muscles. On the left side it had not burrowed in any direction. In the spinal canal it had passed between the vertebral bodies and their posterior common ligament both upwards and downwards; upwards to the superior limit of the seventh cervical, and downwards lower than the inferior limit of the third dorsal. (The sixth and seventh cervical and the first, second, and third dorsal were removed at the autopsy and set aside for subsequent examination; thus the opportunity was lost of making out if the above-mentioned channel communicated through an intervertebral foramen with the abscess on the left side of the chest.) The posterior common ligament was separated in nearly its whole breadth; in the middle line it remained bound down in places, so that a double channel freely intercommunicating was formed. In this channel was a layer of friable material, partly broken down, measuring in its thickest part about a line and a half. The said ligament and the membranes were all deeply stained, and the antero-lateral columns of the cord were congested. In the thorax there were firm pericardial adhesions throughout, and between the adherent layers were four or five collections of cheesy pus varying in size from a pea to a hen's egg, the largest of them being to the outer side of the cardiac apex. The left pleura was adherent throughout, but readily detached, and there were perihepatic adhesions. The thoracic and abdominal organs were healthy.

Remarks.—In the year 1882 there occurred at this infirmary 125 deaths, and of these the above three occurred from caries of the spine in tailoresses, who followed an arduous occupation of twelve hours

a day in the same stooping position. These cases seem in a striking manner to bear out Mr. Hilton's statement in "Rest and Pain":—"I must state my belief that the majority of the cases of primary disease of the spine in children, and almost all those in adults, are the result of exercise persevered in after fatigue, etc."

STANLEY HOSPITAL, LIVERPOOL.

INTESTINAL OBSTRUCTION; BENEFICIAL ACTION OF THE EXTERNAL APPLICATION OF BELLADONNA.

(Under the care of Dr. COSTINE.)

For the following notes we are indebted to Mr. Charles Morton, house-surgeon:—

A man, aged thirty-five, was admitted on December 28th, 1882, suffering from obstinate constipation. The bowels had not been opened for fourteen days, with the exception of a little scybala passed after enemata occasionally. Until a fortnight ago the bowels had always been open regularly. The insuperable constipation had not been accompanied at its commencement by any acute symptoms, nor had blood ever been passed per anus. There was no history of his ever having had hepatic colic. There had been loss of flesh of late. For a fortnight he had vomited occasionally; had had much pain in his abdomen. The belly was much distended, but the walls were not tense. At times there was a soft, defined swelling in the right iliac region about the size of the cæcum. No lumps or bowel could be felt; there was no hernia. Nothing abnormal could be felt per rectum; a large quantity of fluid could be injected. He had taken all kinds of purgatives before admission, without any action of the bowels being produced by them. Ordered one grain of opium every six hours; also cold, strong beef-tea and milk in small quantities often. Next day he was free from vomiting and pain in the abdomen; bowels not open. On the 31st there was great prostration; the pulse was intermittent, frequent, and there was fecal vomiting; indeed, death seemed fast approaching. Ordered plenty of strong beef-tea and six ounces of brandy in twenty-four hours, and one ounce of belladonna ointment spread on a large poultice to be applied over the abdomen, and repeated frequently. Great emaciation had taken place in the last few days.

On Jan. 1st he had a large liquid evacuation. There was no pain in the abdomen, though the fecal vomiting continued. He seemed a little less collapsed. On the following day the bowels were still freely open, and there was no vomiting.

From this time he continued to improve; but on the 5th and 6th the bowels were not opened, and there was a return of rather severe abdominal pain. Castor oil failed to open the bowels; but the constipation and pain were removed by return to the old treatment of the external application of belladonna and the internal administration of small doses of opium. He left the hospital on Jan. 10th.

Remarks by Dr. COSTINE.—It is often very difficult to say in any case whether recovery be due to any special method of treatment; and perhaps in this case the obstruction might have been overcome without the belladonna, but for fourteen days the bowels were unable to empty themselves downwards, the patient was evidently dying, and the only alteration in treatment other than the application of the belladonna was to give brandy, so that I think the strong probability is that the belladonna saved his life. The belladonna was first applied during the afternoon, and the bowels were opened the same evening.

LEEDS PUBLIC DISPENSARY.

ENCHONDROMA OF BOTH LUNGS, WITH SECONDARY GROWTH IN BRAIN; NECROPSY; REMARKS.

(Under the care of Dr. CHURTON.)

For the following notes we are indebted to Mr. P. J. Hudson, M.B., senior resident medical officer.

Annie S—, aged eighteen years, came under observation on August 4th, 1882, complaining of shortness of breath and severe cough. The family history was good, except for the loss of a brother from consumption (?). The patient had always been delicate, and she had the left leg amputated four years ago for diseased knee. The nature of the disease could not be ascertained, only that matter had come away from the joint for months prior to the operation. For the last sixteen months she had been getting thinner and had had night sweats, but continued to work till a fortnight before admission, when she discontinued, owing to pain in the right chest, dyspnoea, and spitting up of bloody phlegm, attributed to frequent chills caught at a flax mill. She was a dark, thin girl, of a general icteric tinge, though slight. On examination the right chest presented the usual signs of effusion, there being dullness in front below the third rib on sitting up, below the fourth on lying down, with annulled vocal resonance and fremitus and absence of breath sounds. Above this point the latter were faintly audible, also a few moist *râles* on deep inspiration. Behind there was dullness from the third rib downwards; above this fair respiration, but resistance on percussion. No rub was heard or pain felt on deep inspiration. The left chest throughout gave a sense of resistance on percussion, and there was exaggerated breathing in front, but rather distant behind. Heart and other organs healthy. Temperature 101.4°. A hypodermic needle withdrew from the right chest fluid deeply blood-stained, and showing microscopically only many white and a few red blood-discs. The sputum was uniformly tinged with blood, and contained no elastic tissue. The symptoms not being urgent, she was ordered nutritious food, linctus morphine, and to take alternately, every hour and a half, one minim and a half of the solution of perchloride of mercury, and five-eighths of a minim of tincture of green veratrum.

Aug. 7th: Rather sick after the green (veratrum) medicine. Temperature 101°, morning and night. Has night sweats.—14th: Breath-sounds over right chest more distant; other signs as before; no sickness; temperature 100°.—20th: Can lie only on the right side; suffers from shortness of breath; gums slightly touched. There is fair resonance now from the fourth rib upwards in front, and faint respiration is heard throughout. The dullness in the axilla extends from the fifth rib downwards and behind from the fourth rib, and respiratory sounds are more audible than on the 14th. There is a rub on deep inspiration at the right base. To continue the medicines every three hours (i.e., half the quantity), and have a blister over the lower right chest behind.—22nd: Pain returned; some sickness. To take the medicines thrice daily.—25th: Mr. Hudson removed seventeen ounces and a half of blood-stained fluid from the right chest by the aspirator, a quantity being left. Only blood-discs were detected in this fluid.—26th: Feels easier, and has no dyspnoea; can lie on either side. Ordered one drachm of tincture of quinine with decoction of cinchona, an ounce thrice daily.—28th: The blood-stained expectoration, though slight, continues daily. Has much frontal headache; and is very sick. To have an effervescing

draught, with three minims of dilute hydrocyanic acid every two hours.

Sept. 1st: Signs of fluid in chest as before. Sweats much, but has no sickness. To have the quinine mixture again.—4th: Slight twitching of left arm and hand.—5th: Had a fit last night, being unconscious an hour, and the left arm and hand moved backwards and forwards. Is now quite sensible, complains greatly of frontal pain and of the left fingers being numb, though moved easily.—6th: Has slept well, but on waking felt the left arm heavy, and cannot now raise it or move the fingers. No anæsthesia. Reflexes abolished almost. Differences of temperature felt. Left stump normal, and no other paresis. Heart normal.—9th: Can move the arm from the left shoulder.—12th: Much cephalalgia, the pain shooting over the right temple and back to the occiput. Very sick, independent of food. Temperature normal. To have whisky and laudanum cloths to the head, and the effervescing draught with one drachm of the tincture of hop every two hours.—16th: Sickness relieved. Pain in the head and chest worse. To have morphia pill (one-quarter of a grain) every three hours.—24th: No pain or sickness for four days. To take ten grains of calcium hypophosphite with tincture of nux vomica every four hours.—30th: Had a second fit in the night. Has had great pain in head for two days and attacks of blindness. The left upper extremity remains as before, but is often attacked with twitchings. Distant respiration throughout the chest, other signs as before. Bowels not confined. Twenty grains of the bromide of sodium to be taken with the above draught every two or three hours.

Oct. 2nd: Is sinking, but has very much less pain since the last medicine.—3rd: Takes the bromide with brandy every hour and a half, and is quite easy. Temperature normal. Is quite sensible.—4th: Died comatose.

Necropsy, thirty-six hours after death.—The body was fairly nourished. There was no wasting of the left arm. On opening the chest the pericardium contained two ounces of serum. The heart and its large vessels were normal. There was a quantity of dark fluid in the right pleural sac. The right lung was much retracted in front, and was found partly fixed posteriorly and of a bony consistence, and was removed with difficulty. It weighed fifty seven ounces. The posterior portion or root of the lung was one mass of ossified tissue, and similar growths were scattered throughout the anterior portions. The left lung had a few nodular growths of the same character, mostly at its borders and root. The bronchial glands generally were much enlarged, and very hard. Except where adherent to the right lung behind, the pleura was free from the growths. The abdominal viscera were healthy; the vertebrae were normal. The skull cap being removed, and the dura mater divided, a growth almost round in shape was found situated on the surface, and in the substance of the right cerebrum as follows:—It was three-quarters of an inch from the superior longitudinal sinus on its left, extending to the interparietal fissure on its right. Posteriorly it reached to one-eighth of an inch from the parieto-occipital fissure, and anteriorly to the junction of the superior with the middle frontal convolution. It thus roughly occupied the place of (1) the superior parietal lobule; (2) ascending parietal convolution; (3) ascending frontal convolution; and (4) superior frontal convolution. It could be shelled out of its bed without lacerating the brain substance, and weighed nine drachms. Rest of brain normal.

A section of the lung growth showed it to be

ordinary osteo-chondroma. No lung structure was visible in the densest portion, but trabeculae and medullary spaces, the former of which were calcified, and contained angular cells, some surrounded by cartilage shells, others mature and partly calcified, the latter (medullary spaces) fibrous stroma. The cranial growth contained principally the latter and many bloodvessels, together with scattered centres of cartilage cells. Portions of the lung growth on being decalcified by chromic acid showed partly compressed and obliterated infundibula, etc., in the places least invaded, whilst others were almost dissolved by this process.

Remarks.—The hæmorrhagic character of the pleural fluid, together with the history of a (?) suppurating knee-joint four years ago and the general symptoms, led to the diagnosis of miliary tubercle of the lung rather than from direct physical examination. The fixed cranial pain following on the chest mischief, and itself followed by left brachial monoplegia, led to the diagnosis by Dr. Churton of a secondary growth in the brachial motor area in the cortex of the right cerebral hemisphere. It was impossible to diagnose osteo-chondroma of lung without a definite history of the former (?) knee disease, as no characteristic cells were found in the sputa or pleural fluid, and no needle probably could have withdrawn anything characteristic from the lung growth itself, nor were there any pressure symptoms or glandular enlargements externally. The multiple nature of the growth makes it still more likely to have been secondary to an osteoid sarcoma of the lower end of the femur four years ago. It is worthy of note that the convolutions occupied by, or obliterated by, the cerebral growth, correspond to those which, when stimulated in the dog (according to Hitzig and Fritsch), cause extension, adduction, flexion, and rotation of the opposite fore limb, and in the monkey, according to Ferrier, the various complex movements of the opposite arm, especially following irritation of the posterior portions (posterior parietal lobule, posterior end of superior frontal convolution, etc.), and which were affected by the cranial neoplasm which had not advanced anteriorly enough to affect the opposite leg, or, rather, stump.

BROMLEY COTTAGE HOSPITAL, KENT.

CRUSHED FOOT; GANGRENE OF TOES; SECONDARY AMPUTATION AT ANKLE (SYME'S OPERATION); RECOVERY.

(Under the care of Dr. HERBERT J. ILOT.)

W. T—, a boy aged fourteen, was admitted on the evening of March, 10th. He had been playing with other boys about the goods yard at the Bromley Station. Some of the porters were engaged in shunting trucks, and, it being dark, did not observe the boys. W. T— was knocked down by a truck, the wheel of which passed over his foot.

On admission, it was at once evident that a very severe injury had been sustained. The anterior part of the foot was pale; the posterior about the heel swollen and discolored. The curvature of the instep was increased. The boy could move his toes, and the sensation of the skin over the toes was not lost, although diminished. There was fracture of the second and third metatarsal bones, with partial displacement forwards of the distal bones of the tarsus; there was a lacerated wound about four inches in length obliquely across the dorsum of the foot, in which the extensor tendons could be seen, uninjured, as well as the dorsal artery of the vein of the foot; there was also a wound admitting the forefinger on the inner side

of the heel, extending down to the os calcis. Pulsation could be felt in the posterior tibial artery. Although the injuries were so severe it was determined, after consultation, to make an attempt to save the foot, in view of the patient's youth and station in life. After the parts had been well cleansed with carbolic lotion (1 in 20) a drainage-tube was inserted along the principal wound, which was closed with silver-wire sutures. The foot was placed in good position on a padded back-splint, and gauze dressings were applied under spray. Next morning the toes were bluish, but sensation was better. Free serous discharge soaked through the dressing. Over the stained portions fresh gauze soaked in 1 in 20 solution was placed, with a pad of tenax under the heel.

On March 13th, the wound was dressed under spray. There had been an abundant serous discharge, especially from the wound on the inner side of the heel. The foot was much swollen on the dorsum, where there was a large collection of fluid pent up. This was let out by removing one of the sutures. Pulse 84; temperature 102.6°. On the following day sensation was better. The boy could move his toes freely, and there was no pain; sleep disturbed. Pulse 86; temperature 100.2°. On the 17th, he was still free from pain; sensation in the toes was better; there was much discoloration, though without swelling or fetor. He passed a quieter night, but wandered at times; he had bad dreams. Pulse 88; temperature 98.8°. On the 18th, the foot was dressed under spray with gauze dressings. A large bleb on the dorsum was punctured and clear serum was let out. The anterior part of the dorsum and the toes were much discolored; the wound looked healthy; the skin at the margin of the discolored part of a purplish-red color; the heel tissues were warm and healthy in appearance; the ankle and leg were of a yellow color from bruising, not swollen. Pulse 100; temperature 99.2°. On the 21st, a consultation was held by the honorary medical officers, Drs. Beeby, Playfair, and Ilot, as to the advisability of amputation at the ankle. It was found that although there was a large slough on the outer side of the dorsum of the foot, and the three outer toes were much discolored and threatened to become gangrenous, the tissues on the inner side, as well as the heel and sole of the foot, were warm and healthy; and the line of demarcation being well defined, it was resolved to defer amputation. The antiseptic dressings were discontinued, and the foot enveloped in a charcoal poultice after the parts had been washed with carbolic lotion. The foot was placed on an iron back-splint and swung. On the 28th another consultation was held, and it was decided to amputate, as the gangrene was extending to all the toes, and the slough on the dorsum of the foot having separated, leaving an extensive granulating surface with no prospect of a useful foot. The foot was therefore removed the same afternoon by Syme's operation at the ankle. The patient was placed under the influence of an anæsthetic mixture (alcohol, ether, and chloroform). The heel flap was dissected down from the os calcis, which was done with ease, the tissues being much thickened. A short dorsal flap of sound integument was also formed. Both malleoli and the articulating surface of the tibia were removed by a frame saw. The anterior tibial and the plantar arteries were secured with carbolized catgut ligature. An opening was made through the centre of the heel flap, through which an india-rubber drainage-tube was passed. The flaps were united by silver-wire sutures. The dressing was lint soaked in carbolic oil, the whole stump being enveloped in salicylic wool. The leg was laid on a pillow and protected from pressure by a cradle.

The boy was sick a little after operation, and being in pain had eight minims of tincture of opium. Pulse 76; skin warm. A second dose of opium was given at 10 p.m. He slept well during the night. Next morning he was thirsty and feverish, and had had no action of the bowels. Pulse 128; temperature 102.8°. There was no oozing through the dressings. Ordered a dose of white mixture, with milk and cooling drinks.

On March 30th the stump was dressed, looking very well; union taking place; no tension or irritation. The same dressing was reapplied and the limb swung. Temperature 99.2°. Ordered a quinine mixture, with diet of beef-tea, milk, and milk pudding.

On April 3rd some of the sutures were removed; the flaps were gaping a little on the outer side; two small sloughs of cellular tissue were removed, one through the opening in the heel flap left by the removal of the drainage-tube. The flap was supported by strapping, and dressed with lint, soaked in terebene oil. Pulse and temperature normal, appetite and sleep good. He was put on ordinary diet.

From this time the healing process went on uninterruptedly well; a sound fleshy stump was formed, and the patient was discharged on June 3rd. Being promised with a letter for the Surgical Aid Society he was supplied with a socket lacing round the knee, and terminating in a rounded flat extremity. With this he gets about remarkably well, earning his living as house-boy and messenger, running and walking with ease, and without any limp. He can bear any pressure on his stump, which is quite painless.

UNIVERSITY COLLEGE HOSPITAL.

FIVE CASES OF SUBCORACOID AND ONE OF SUBGLENOID DISLOCATION OF THE HUMERUS REDUCED BY KOCHER'S METHOD.

(Under the care of Mr. C. HEATH.)

For the following notes we are indebted to Mr. W. Chisholm, house-surgeon, who effected the reduction in all the cases except the first.

In *THE LANCET* a short time since attention was called to a paper on a method of reducing dislocations of the shoulder, read by M. Kocher at the meeting of the International Congress in London. Referring only to the subcoracoid form of dislocation, M. Kocher directs that for its reduction the surgeon should sit on the left of the patient, then the elbow-joint is to be flexed at a right angle, and the joint firmly pressed against the side of the chest. Next, while the elbow is held in contact with the body, the arm is to be slowly, gently, and steadily rotated out until firm resistance is encountered; then while this rotation is maintained the arm is to be raised forwards, and a little in, and, lastly, to be rotated in, and the hand brought towards the opposite shoulder. This plan has been tried in six of the cases which have come to University College Hospital during the last five months.

CASE 1.—A muscular young adult, with left subcoracoid dislocation. An attempt was made to reduce it with the knee in the axilla, but as this caused much pain the patient was given an anæsthetic. While this was being administered it was decided to give Kocher's method a trial. The patient lying on his back, Mr. Heath flexed the elbow at a right angle, pressed it firmly against the side of the chest, the arm was then rotated outwards, and the head of the bone slipped into the glenoid cavity before the forward movement of the arm was commenced. This case came on a day just before

Mr. Heath's expected visit, and was kept so that the students might see it reduced.

CASE 2.—An adult female, with right subcoracoid dislocation. This was the first case attempted by this method without an anæsthetic. The patient was seated in a chair, and an attempt was made to reduce the dislocation in the manner described. This was unsuccessful, and the patient was told to lie down on the couch with a view to having an anæsthetic. While in this position, and before giving the anæsthetic, another attempt was made at reduction by manipulation, the arm being more firmly pressed to the side. On rotating outwards a little grating was felt, and just as the forward movement of the arm was commenced the head of the bone slipped into the normal position. Patient experienced very little pain.

CASE 3.—A young male adult with right subcoracoid dislocation. He said his arm had been "out" before. In this case reduction was effected with the greatest ease without an anæsthetic, patient being seated in a chair; the head of the bone returning to the glenoid cavity at the commencement of the forward movement.

CASE 4.—Similar to Case 3, except that there had been no previous dislocation.

CASE 5.—A coal-heaver, a muscular man, with a right subglenoid dislocation. Patient was seated in a chair and reduction effected with some trouble, and only after the elbow was very firmly pressed against the side of the chest; at the commencement of the forward movement the bone slipped into its place.

CASE 6.—A male adult, a muscular man, with right subcoracoid dislocation, was seen about noon. He had been drunk the previous night, and did not know how the injury was caused. In this case until an anæsthetic was given the bone could not be disengaged, and the attempt gave very much pain. When the patient was under chloroform reduction was readily effected. In this case the right hand was brought nearly to the opposite shoulder.

Out of the six cases five were subcoracoid and one subglenoid; and though M. Kocher's paper seems only to refer to the former injury, the subglenoid dislocation was reduced by his method without an anæsthetic. Of the five subcoracoid cases three were reduced without an anæsthetic; but in the first case Kocher's method was not tried until the patient was under chloroform. By this manipulation the margins of the rent in the capsule are relaxed, and the rent opened out, thus allowing the head of the bone to slip readily into the glenoid cavity.

QUEEN'S HOSPITAL, BIRMINGHAM.

GUMMATA OF THE TONGUE IN HEREDITARY SYPHILIS.

(Under the care of Mr. JORDAN LLOYD.)

H. M.—, aged eighteen, domestic servant, attended the hospital on June 22nd, 1882, complaining of a sore tongue. She was a big, dark, flabby, coarse-skinned girl of nervous habit, with a thick upper lip. Her teeth were rather peggy and rough, but not notched, and there were old white scars at both angles of the mouth, the size of sixpences. She had chronic interstitial keratitis in both eyes. Her father and mother died of consumption (?); one brother only was living, and he had bad eyes. There was no history of acquired syphilis in the patient. Her tongue had troubled her for nearly two years. At its left side, at about an inch from the tip, was a deeper ulcer, irregularly circular, the size of a threepenny-piece, with clean cut edges and dirty yellow base, surrounded by a zone

of induration, which faded gradually away into healthy tongue tissue. Posterior to this ulcer, in the middle of the left lateral half of the tongue, was an irregular cavity, filled up by a characteristic gummatous nodule, of the size of a horsebean and like yellow indiarubber. There was another ulcer, similar in appearance to that previously described, situated at the edge of the right side of the organ. These ulcers, of which she had had similar ones, began as nodules in the tongue; they then ulcerated on the surface, exposing yellow masses. She had no decayed teeth, nor any enlarged glands. A mixture containing five grains of iodide of potassium, with ammonio-citrate of iron, was given three times a day, and a borax gargle was ordered for the mouth.

After a few days the gumma softened and came away, and by Sept. 14th all the ulcers of the tongue were healed, leaving the tongue rather enlarged, with ragged, but perfectly soft, edges. The keratitis disappeared a few weeks later.

She was seen on January 18th, 1883, and continued quite well. The tongue was corrugated at its edges, and had several cicatrices in its anterior third. Its entire surface, except for the scars, was perfectly natural and quite free from the well-known appearance resulting from superficial glossitis.

Remarks by Mr. LLOYD.—The occurrence of gummatous tumours in the tongue as a result of hereditary syphilis is sufficiently rare, I trust, as to warrant me in placing this well-marked case on record. I can find few writers even who refer to them. Fairlie Clarke, in his work on "Diseases of the Tongue," mentions in a casual manner, at the end of a section upon one of the forms of syphilitic tongue disease, "that tumours are seen in the tongues of children which are evidently due to inherited syphilis." Dr. Drysdale records a case in the *Medical Press and Circular* for May 19th, 1875:—"A girl, aged sixteen years, with strong evidence of inherited syphilis, who had several nodules at centre of tongue." There was no difficulty in diagnosis in my case, the keratitis, the cicatrices at the angles of the mouth, the yellow rubber-like mass in the tongue, all pointing to the syphilitic diathesis. It is interesting to note the age at which the growths appeared, and also the perfectly healthy condition of the surface of the tongue, apart from the nodules and ulcers. Drysdale's case is reported as having the glazed tongue so commonly met with in the syphilized adult. The result of treatment still further establishes the correctness of diagnosis.

SEAMEN'S HOSPITAL, GREENWICH.

TWO CASES OF ULCERATIVE ENDOCARDITIS; NECROPSY.

For the following notes we are indebted to Dr. Penny, house-physician.

CASE 1. (Under the care of Dr. Curnow.)—William McC—, aged twenty-nine, was admitted on August 10th, 1882. He had ague nine years ago, and had had a cough for the past year. He was in the Seamen's Hospital at the end of June with pneumonia of the left base. Nothing abnormal could then be discovered about the heart. On August 4th he was taken ill with "ague" and had shivered several times afterwards.

On admission he was very ill; pulse collapsing. The heart's apex beat was found in the fifth space just inside the nipple line. A diastolic murmur was plainly audible to the inner side of the apex beat, and an indistinctly murmurish sound with the systole at the apex. Respiration was very rapid and shallow. Some moist sounds were heard at both bases. There was prolonged expiration

at both apices. Pulse 130; temperature 100.2°; respiration 60 to 70. Spleen felt just below the margin of the ribs. Urine, sp. gr. 1022, no albumen.—August 12th: Heart sounds muffled at apex. No distinct murmur could be made out. Second sound very accentuated at the base. Pulse still collapsing. Fine râles generally through the chest. Morning temperature 99.1°; evening temperature 101.2°.—13th: Much worse. Physical signs as before. Morning temperature 100°; evening temperature 100.6°.—14th: Respiration very rapid and distressed. Physical signs as before. Morning temperature 100°; evening temperature 101.6°. Urine, sp. gr. 1018. A slight amount of albumen now present.—15th: Much cynosis. Bowels open for first time since admission, loose. Morning temperature 101°. Died 3.30 p.m.

Necropsy.—The heart weighed fifteen ounces, relaxed, left ventricle dilated and hypertrophied. A large rounded mass of worm-like granulations depended from the angle of junction of the posterior and the left anterior segments of the aortic valve, and from the adjoining left half of the left anterior segment, this latter structure being enormously stretched; so that while the worm-like mass hung from its ventricular surface its aortic surface formed a cup-like hollow, in the centre of which two perforations had occurred, extending through the valve and through the mass of granulations beneath and opening into the ventricle. The granulations formed a mass of the size of a large hazel nut, and almost filled up the aortic orifice. Below the line of attachment of the base of the affected valve the tissue of the ventricle was much softened and pulpy, and from this ulcerated patch extended upwards in the middle coats of the aorta, a condition of extreme softening of the tissues, so that a probe could be easily passed along the softened tract. About one-third of an inch above the aortic orifice the probe thus passed entered the cavity of the aorta through an ulceration of the inner aortic coats, about a quarter of an inch in length, while exactly opposite this ulcer on the other side of the aorta was a smaller deep ulceration, quite unconnected with the softened tract running up from the heart, and extending nearly through the whole thickness of the aorta, leaving only a thin part of the outer coat intact, and this, dark in color, and bulging outwards, formed a minute aneurism which must soon have ruptured had life continued. The remaining valves, including the parts of the aortic not mentioned above, were quite healthy, and no sign of old-standing mischief could be found. The lungs were bulky, showing here and there star-like patches of pigmented fibroid tissue; tubes rather dilated; some of the lung tissue highly congested and almost airless; left lung adherent all over; spleen much enlarged; a single large wedge-shaped recent embolic patch in upper part; kidneys seemed healthy; liver rather soft; mucous membrane of stomach showed some small ecchymoses; the brain was normal.

CASE 2. (Under the care of Dr. Carrington.)—Horace L—, aged twenty-two, ship's steward, was admitted July 19th, 1882. The patient had scarlatina when ten years old, followed by dropsy, and (according to the doctor) heart disease. When fourteen years old he had rheumatic fever. He has also had small-pox and yellow fever. On July 13th he became ill with diarrhoea and pains in the head and chest, and delirium at night.

On admission he was too ill to give any account of himself. The heart's apex beat was found in the sixth space, two inches outside the nipple line. A very loud systolic murmur was heard over the aortic valves and upwards and to the right over the ascending aorta, though with diminishing loud-

ness downwards over the cardiac area, but becoming again somewhat intensified near the apex. A diastolic murmur was also present at the base, heard downward along the sternum. Cardiac pulsation very marked; pulse very collapsing, 116 per minute. Spleen felt about an inch below the margin of the ribs. Liver dulness extended two inches below the rib margin in the nipple line. Respiration very hurried (48 per minute); coarse breath sounds both sides. Complexion sallow, almost yellowish; sordes on lips, tongue dry and brown. Urine, specific gravity 1010, contained albumen in large amount, but no bile, and gave a doubtful reaction with the guaiacum test for blood; temperature 103° F.

July 20th.—Morning temperature 101.8°; pulse 128; respiration 56. Urine gave a decided blood reaction; no casts discovered. Evening temperature 102°; pulse 138; respiration 65.—21st: Morning temperature 101.2°; evening temperature 101°. Died 10 P.M.

Necropsy.—Pericardium contained about an ounce of blood-stained fluid. The heart weighed twenty-six ounces, and was enormously dilated and hypertrophied on both sides; the aortic valves were shrunken, contracted, and highly incompetent. The mitral orifice was contracted, and only admitted two fingers. On the posterior wall of the left auricle was a round patch of ulceration about the size of a shilling; its lower margin touched the rim of the mitral orifice along the posterior border, of which a thin line of ulceration extended, running about half-way round the opening. On the ventricular aspect of the larger mitral valve was a second patch of ulceration about the size of a threepenny piece, which extended upwards into the angle between the two corresponding aortic cusps; a third, and yet smaller, ulceration occupied the angle between the two anterior aortic cusps, extending downwards slightly on to the ventricular septum. The surfaces of the ulcers presented a similar appearance, being uneven, indeed, almost flocculent, and not sensibly depressed below the general surface. The lungs were adherent on both sides by old adhesions; both lungs highly congested and oedematous, the greater part sinking in water and almost pneumonic in appearance. The liver was large, pale, soft and opaque; a few ecchymotic points in the interior. Spleen much enlarged, almost diffuent; presented several large recent embolic patches. The kidneys weighed fifteen ounces, soft, so that the capsule, unless carefully removed, tore away the cortex. On section the organs presented thickly scattered points of ecchymosis, each spot being surrounded by an area of intense injection, the bases of the pyramids and the cortical portion being chiefly affected. Several firm, yellowish bands of tissue ran through to the cortex, extending from the base of the pyramid the surface (? old infarcts). The mucous membrane of the stomach showed numerous petechiæ; membranes of the brain injected.

SUSSEX COUNTY HOSPITAL.

TWO CASES OF POPLITEAL ANEURISM.

(Under the care of Mr. BLAKER.)

For these notes we are indebted to Mr. B. Scott, house-surgeon

CASE 1. Popliteal Aneurism cured by Compression of the Femoral Artery.—R. G—, aged forty-two, bricklayer, was admitted September 4th, 1882, with a pulsating swelling in the right popliteal space. Pain and swelling came on about two months previous to admission. For the last three weeks he had stayed in bed, owing to increase of

pain. The pain had kept him awake at night. He had had rheumatic fever. There was no history of how to account for the trouble.

On admission the following notes were taken. There is a swelling about as large as one's fist in the right ham. It can be felt pulsating behind and through the muscles on the inner side of the knee. It descends very low down between the heads of origin of the gastrocnemius. It is four inches and a half in length and three in breadth. There is a distinct aneurismal bruit. The leg is hotter on this side. The subcutaneous veins are enlarged. The tibial arteries at the ankle beat indistinctly. There is pain in the upper end of the tibia. The general health is good. To be kept in bed with his leg resting on its outer side on a pillow and flexed at the knee; and to have the ordinary meat diet.—Sept. 9th: The swelling is rather smaller. Fish diet ordered.—13th: Swelling harder and smaller. He now has a pint of gruel or arrowroot, a pint of beef-tea, and a pint of milk in the twenty-four hours.—20th: The aneurism is to be treated by compression applied to the femoral artery. The skin over the artery has been shaved, and sweet spirits of nitre has been rubbed in daily of late. The course of the vessel is marked out. Compression is accomplished by means of a thick brass wire, straight except at the top, where there is a gentle curve. To its lower end is soldered a circular piece of lead, convex below. This is padded thickly with wash leather. The apparatus is placed on the artery and lead weights are slipped on to the wire. It is kept in place by being tied with bandages round its curved upper end on to a body cradle. The brass wire is a foot long. The minimum weight which stops the circulation is 14 lb 14 oz. The whole can be made to slide up and down along the artery when it is necessary to alter its position without allowing any pulsation below. Five inches of the femoral artery below Poupart's ligament are available in this way.—21st, 10 P.M.: Compression, which has been continued now for thirty-six hours, is stopped. The tumour is hard, smaller, and quite free from pulsation. The patient has had very little inconvenience from the treatment. The weight has been shifted every quarter of an hour. It has been quite needless to give any sedative. He is an exceptionally good patient.

Oct. 12th.—He has not yet got up. The tumour decreases and is hard. No recurrence of pulsation. His diet is now being gradually increased.

Nov. 26th.—To-day he gets up for the first time. He has no pain now. The aneurism is felt converted into a hard non-pulsatile sausage-shaped tumour.

Nov. 28th.—Left the hospital.

CASE 2. Popliteal Aneurism cured by Manipulation and Rest.—C. W—, aged thirty-seven, laborer, was admitted on Nov. 24th, 1880, with an aneurismal swelling in the right popliteal space. He was a fairly healthy man; pulse 72, rather hard; had been married twelve years; and had had no children. He had a sore on the penis twenty years ago, of which the scar remained. There was no history of any secondary symptoms. About six weeks before admission, after walking about on a very wet day, he noticed pain at the back of the right knee. He discovered very soon afterwards a swelling there. This has never gone. He has continued doing his work.

On admission the following notes were taken:—There was a hard pulsating swelling felt in the popliteal space. It was about the size of a walnut. The tumour expanded from side to side. There were no signs of inflammation. It felt as if it contained some clot. No bruit was heard. On raising the limb the pulsation was diminished, and

less force was required on the femoral artery to stop the pulsation.

Nov. 26th.—Yesterday the limb was raised, and the tumour manipulated in various ways. To-day the pulsation has ceased entirely, and the tumour is harder.

Dec. 1st.—There is no pulsation, and the tumour is still more hard.

Jan. 12th, 1881.—There is now a small hard cord in the course of the artery.

On Feb. 5th he left the hospital.

COUNTY DONEGAL HOSPITAL.

CASE OF LARGE SPINAL ABSCESS FILLING THE ABDOMEN, OBSTRUCTING VENA CAVA; ASPIRATION; INJECTION OF TINCTURE OF EUCALYPTUS; CURE.

(Under the care of Dr. TRAVERS B. BARTON.)

RICHARD McL—, aged sixteen, was admitted on Oct. 1st, 1882. He had suffered from spinal curvature for five years. Two years ago the right side began to enlarge close to the umbilicus; since then the abdomen had gradually increased until the breath got short, when he sought advice. The abdomen was enormously distended and full of fluid; dulness from ribs to pelvis on right side to within an inch of the median umbilical line; the intestines were pushed *en masse* to the left side. The superficial veins were very prominent, some as large as a lead pencil in diameter; respiration was short and difficult; slight jaundice was present; measurement round umbilicus $32\frac{1}{2}$ in. The abscess seemed inclined to point in the nipple-line below the ribs. There had been extensive caries of the spine in the dorsal region; at least five vertebrae were implicated, their spines forming a prominent angle.

On the 4th sixty-nine ounces of greenish colorless pus were drawn off by an aspirator, the needle being introduced below the ribs in the nipple-line. Evening temperature 98° ; pulse 72. The abscess appeared about half empty. The needle became choked. The next day the veins were almost invisible; pulse and temperature normal; breathing comfortable; circumference round umbilicus $29\frac{1}{2}$ in. On the 10th the swelling was aspirated and eight ounces of pus withdrawn. The needle choked. On the 15th aspirated to six ounces, and the needle, having again become choked with flakes of pus, was removed and then reintroduced, but it at once became blocked. Three drachms of tincture of eucalyptus were injected through the needle. On the 21st seventy-six ounces of creamy pus were removed, and the abscess was completely emptied. The pus was of a uniform consistence, and flowed slowly but continuously through the needle. Measurement round umbilicus $27\frac{1}{2}$ in.

On Nov. 11th there was no appearance of the abscess filling. Sayre's jacket was applied, and the patient was allowed up. On the 24th the jacket was cut and reapplied, he having become too fat for it.

The patient was discharged cured on Jan. 13th of this year, with a fresh plaster jacket applied. Intestines in both sides of abdomen. No appearance of abscess anywhere. He has gained flesh, and wished to go home to work.

Remarks by Dr. BARTON.—There are some points of interest in this case—viz., the size of the abscess simulating ascites, it having taken five years to form; so little inconvenience was caused that the patient had walked six miles the day before admission; and, lastly, the curious effect the eucalyptus had upon the flaky pus that could not be removed through the aspirator needle. I have not yet heard of any other case in which eucalyptus

has been used in this way, and with a similar result. The pus removed (six days after the injection) had a strong smell of the eucalyptus.

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

The Etiology of Scurvy.—Case of Scurvy with Dilatation of the Heart and Retinal Hemorrhage.

THE ordinary meeting of this Society was held on February 27th, Mr. John Marshall, F.R.S., President, in the chair. Two papers were read dealing with the subject of scurvy. Mr. Neale, late Medical Officer to the *Era* Expedition, contributed the first paper, which was listened to with great attention, and excited a very prolonged and interesting debate, which was shared in by Sir. W. Smart, Dr. John Rae, Dr. De Chaumont, Dr. Colan, Dr. Donnett, and others. The second paper consisted in the record of a case of scurvy associated with dilatation of the heart and retinal hemorrhages, conditions attributed by the author, Dr. Hale White, to the anemia present in the disease. At the close of the meeting, the President stated that further opportunity would be offered at an early meeting for the discussion of the questions raised by Dr. Hale White, as other papers on the pathology of scurvy were to be read before the Society.

Notes on some points in the Etiology of Scurvy, by Mr. W. H. Neale. The object of the paper was to discuss the etiology of scurvy, and to consider whether the experience of the late *Eira* Arctic Expedition could throw any light on the question as to how scurvy may best be prevented during an Arctic winter. The recognized predisposing causes of scurvy were bad hygienic conditions, long confinement, want of exercise, monotony, anxiety, exposure to cold and fatigue, to which might be added, in the opinion of the author, the use of an inferior quality of meat, whether preserved or not. The exciting causes were the insufficient supply of fresh, or of good preserved, vegetables, and, in default of vegetables, the want of lime-juice. Anæmia was one of the first symptoms of scurvy, and it was not difficult to account for its production if it were remembered that the life led by a body of men shut up in a ship for at least six months must lead to a deterioration of the quality of the blood. Though every attempt was made during the last Government expedition to provide for good ventilation, the general opinion was that the results were not satisfactory. With regard to the action of an inefficient quantity of vegetable food, statistics were very contradictory. The author proceeded to compare the dietary of the two most recent English expeditions to the Arctic regions. In the expedition under Sir George Nares the hygienic conditions, though not entirely satisfactory, were so good that the outbreak of scurvy could not be attributed to any defect in them, and compared favorably with those under which the crew of the *Eira* passed their winter. With regard to diet and ventilation, however, there were distinct differences in the two cases. From a consideration of the dietary, it was evident that the absence of scurvy in the *Eira* expedition could not be ascribed to the employment of a larger total weight of food, and in particular not to the use of a larger quantity of vegetable food, nor to lime-juice, which was not used for a whole year. No case of scurvy occurred among the crew of the *Eira*. But the diet of the two expe-

ditions differed widely in the kind of meat used; in the Government expedition the crews lived almost entirely on preserved meats, while the crew of the *Era* lived exclusively on fresh meat from animals killed on the spot. All flesh obtained in the Arctic regions can be kept in a state, though frozen, chemically like that in which it was when the animal was killed, and must therefore supply to the body those ingredients which are known to be diminished in scurvy far more readily and abundantly than can preserved meats. The importance of using the blood as well as the flesh was much insisted on. Blood obtained from the jugular vein immediately after death becomes frozen solid before any acid fermentation takes place, and in it exist all the components of healthy blood, some of which are deficient in scurvy. The author made the following suggestions with regard to the conduct of future Arctic expeditions:—1. That the crews should spend the winter in huts rather than on board ship. 2. That the albuminoid food should be abundant, and consist as much as possible of the flesh of recently killed animals. 3. That the meat should be cooked in the form of stews or hashes, to which the blood of the animals should be added. 4. That preserved vegetables should be mixed with every meal, to aid the digestion of the meat, but not because they possess in themselves any special, exclusive, antiscorbutic properties. 5. That lime-juice may be dispensed with if fresh meat can be obtained.

Dr. W. Hale White then read a paper on a case of Scurvy with Dilatation of the Heart and Retinal Hæmorrhages. Out of about twenty cases which were examined at the *Dreadnought* Hospital, only one presented retinal hæmorrhages, and that fell under the author's care. The patient was admitted on Nov. 13th, 1882. He had left Calcutta four and a half months ago, and whilst there had had dysentery. On admission he was very sallow, and his was evidently a severe case; there was swelling of the gums and the usual bruise-like swellings about the body. The apex beat was in the fifth space one inch outside the nipple line, the area of cardiac dulness was increased, there was in the third left intercostal space a loud systolic murmur, the first sound at the apex was muffled, and arterial murmurs were present in the neck. The pulse was weak and almost thready. In the right eye were two large hæmorrhages, one above and one below the disc; they were striated at the margin, and white in the centre. The blood showed only 40·5 per cent. of the normal number of white corpuscles, and only 20 per cent. of the normal quantity of hæmoglobin. The patient remained in the hospital a fortnight, and was treated with lime-juice and put on full diet. He steadily improved; the retinal hæmorrhages became less distinct. The red corpuscles increased to 63 per cent. of normal, and the hæmoglobin to 35 per cent. The basic systolic murmur disappeared, but the apex beat remained in the same position. It was pointed out that this case presented the following points of interest: First, the influence of the previous dysentery in making the attack of scurvy severe, which severity was evidenced by the marked blood changes; secondly, the presence of retinal hæmorrhages, a very unusual occurrence as compared with other anæmic diseases, and which was to be explained by the fact that scurvy as seen nowadays was not severe enough to produce retinal hæmorrhages; and, thirdly, the dilatation of the heart. It was shown that this is the only recorded example of this condition in scurvy, and, considering the close alliance of this disease to other anæmic diseases in which it was known that the heart was fatty, it was presumed that here also this was the cause of the dilatation.

The President said that the chief interest would no doubt be centered in Mr. Neale's paper, in which a decided challenge had been given to the old idea that lime-juice is the main and only antiscorbutic, or at any rate that vegetables are so. Scurvy is induced by diet, not by a mere deprivation of food, but by a lack of some constituent essential to the maintenance of the blood in a healthy state. They required the chemist to tell them if there were any recent facts made out concerning the blood in scurvy, particularly as to its deficiency in salts. Then they required to know what amount of albuminoid food was necessary to prevent scurvy, and particularly the influence of fresh albuminoid food; also whether carbohydrates were beneficial because of the carbon and hydrogen they contained, or because of the salts with which such food was associated, and the nature of the salts that were of benefit. He thought Mr. Neale's suggestion of the use of blood as a diet most valuable, since it is the blood that is at fault. They were honored by the presence of many medical officers of both services who had had experience in this disease, and he would follow the etiquette of the service by calling upon the juniors to speak first.—Dr. Colan said that his experience had convinced him that the essential cause of scurvy was the absence from the food of something which is supplied by fresh vegetables, probably an organic acid, free or combined. He enumerated the characters of the disease, and stated that the worse cases he had in the Polar Expedition were those in which there was hydrothorax and hydropericardium, owing to the heart's action being impeded. The blood may be altered by the addition or absence of ingredients, probably the latter. Assuredly under certain articles of food the blood quickly regains the normal; and of all scorbutic effects the serous effusions are the longest to be removed. The conditions of Arctic life might dispose to the disease; thus in the Nares expedition they were living in extreme cold, 105° below freezing point; were 140 days without the sun, and lived for six months on board without opening a skylight. Added to these conditions were depression of spirits and great physical fatigue, each man in the sledging parties having to drag 220 lb. weight over ice hummocks as large as houses. The great remedy is a sufficient supply of first vegetables and fruits, which contain malic, citric, tartaric, and other acids, and their potash salts, which are probably broken up into carbonates in the system, and supply some necessary element to the blood corpuscles, or albumen. He found lime-juice of the greatest possible service in that expedition. The supply came from Montserrat in the West Indies, and was fortified with 10 per cent. of spirit (it contained twenty-seven grains of citric acid to the ounce, the unfortified juice containing forty-two grains to the ounce). On the sledging expedition it was carried in skins containing eight ounces for eight men daily, and when frozen it was mixed with the pemmican. He insisted upon the pure juice being used, and thought no concentrated forms should be tried. In the absence of lime-juice, he advocated the alkaline citrates, tartrates, and acetates. Pressed vegetables were far less useful, they lost something in preparation, and he doubted if they could ward off scurvy, although a high authority in the French fleet considered that pressed vegetables did retard the progress of the disease. But in spite of the vegetable supply, scurvy broke out in six ships of that fleet, but it disappeared when, after arrival in port, a supply of fresh vegetables was obtained. He thought wine and beer were useful, but ardent spirits harmful. He also agreed with Mr. Neale as to the good derived from fresh meat, which should

be raw, and, if possible, in large quantity; he had given his men the skin of the narwhal and walrus flesh, and it was the best substitute for fresh vegetables, possibly because of the lactic acid in the flesh. He had given lime-juice to Esquimaux suffering from scurvy. Milk also is a very good antiscorbutic. The instances of scurvy occurring on vegetable diet may be due to the fact that the essential salts were absent. He trusted that they would soon cease to talk of the treatment of scurvy in the adoption of preventive measures. Every vessel making a quick passage should have an ample supply of fresh vegetables, and sailing vessels should be made to call at ports to renew their stock, and, if this failed, a ration of lime-juice should be served out, beginning with an ounce per man daily, and if the voyage were prolonged, this might be increased to eight ounces daily. Many cases of scurvy are complicated by inflammation of the lungs, liver, and spleen, which lime-juice cannot avail. In our Polar Expeditions, with all the attendant hardships and fatigue, lime-juice was indispensable; and it would be well if, in addition, there should be added such vegetables as raw potatoes preserved in molasses or in earth, which could again be utilized for sowing mustard and cress. It might also be right to send out a second ship with a supply of sheep, which could be killed and preserved in ice. Most of his men on their return looked unhealthy and blotched, but after a month in England they regained a fresh and healthy complexion. He believed with Mr. Neale, that the fresh air obtainable by the *Eira* Expedition was a great aid. They lived in a hut; but in his ship they had to live for six months in darkness between the decks, with an atmosphere charged with $\frac{1}{4}$ per cent. of carbonic acid besides great moisture. They would have been better off in a hut in spite of the cold, for cold was less harmful than bad air. He reiterated his opinion that the main prophylactic and cure for scurvy was a supply of fresh succulent vegetables or lime-juice or some of the organic potash salts. Next to that was fresh meat. In this he would be borne out by Dr. Ninnis, his colleague in the Arctic regions, who had had great experience in scurvy in other parts of the world, and whose absence that evening he regretted.

Dr. Donnett had never seen a case of scurvy on board any ship to which he had belonged, and his experience of the disease had been amongst seamen landed from merchant ships, often very badly provided with means for preventing the disease. From these cases he had drawn certain inferences as to its etiology—viz., that scurvy results from the absence of some protective influence contained in vegetable food, fresh flesh, and fish. He thought that neither cold, nor fatigue, nor mental despondency would induce scurvy of itself. In the Russian Campaign of 1815, in spite of intense cold, no case of scurvy occurred in the French army. Fatigue, no doubt, predisposes to it. In Markham's and Bowman's expeditions great fatigue was endured, the ice hummocks being represented as a city reduced to ruins by an earthquake. The essential element in diet that is protective of scurvy, the absence of which produced the disease, was probably some acid—e.g., citric, oxalic, tartaric, phosphoric—free or combined with an alkaline base. It was not true that certain races had immunity from the disease; he had seen it in Lascars, Chinamen, Esquimaux, as well as in Europeans. As to the value of lime-juice, he did not think that by itself it would prevent scurvy, but it should be associated with fresh food. Its value was great, however; for before its introduction, in 1795, ships could not put to sea on account of the disease, but five years later, in

Lord St. Vincent's expedition, only ten men had scurvy. He regarded the introduction of lime-juice as a boon parallel to the introduction of vaccination, or to the discovery of the circulation. Fresh meat, when obtainable, was better than lime-juice, and potatoes were valuable. Kane, who suffered dreadfully from scurvy, said that if he had only been able to have frozen walrus he would have laughed at it. Dr. Donnett had examined the men in McClintock's two expeditions, and, although they were a long time separated from their ships, they remained healthy. After eighteen days' journey they shot a reindeer, and consequently were able to have fresh animal food. Contrasting the *Eira* Expedition with the late Polar Expedition, he pointed out that the *Eira* men could do as they pleased, and were not exposed to nearly so much fatigue. He thought that the medical profession should take up the question of scurvy upon merchant ships. The men sign articles with no knowledge of their contents; the captain consults his own interest, and cares nothing about the quality of the food supply; he lays in bad provisions, a few vegetables, and a little lime-juice. The Board of Trade should institute a systematic inspection into this matter, and the certificates should be countersigned after such inspection. The Royal Medical and Chirurgical Society might bring its influence to bear on the Board of Trade to enforce such measures.—Dr. John Rae said that his experience of four years in the Arctic regions—not, to be sure, so far north as Dr. Colan was—had taught him that neither cold, nor work, nor other privations produced scurvy. He had been there in stormy weather, in a temperature of 30° or 40° below zero, without a fire; for in his first year they lived in a stone hut, and the door had to be opened whenever a fire was lighted to let out the smoke. Their food consisted chiefly of venison; they killed but few seal. They were perfectly healthy, and took a good deal of exercise. The confinement in the hut did not affect them. In the spring they started off and travelled some 1,400 or 1,500 miles, 500 miles being so rough that they had to carry everything on their backs, for the sledges could not be dragged over the high and rounded hummocks of ice. It was much harder work carrying fifty or sixty pounds' weight than dragging twice that amount. They got short of food, and consumed even the bones and claws of the few ptarmigan that they shot, but did not contract scurvy. They had no spirits or wine, only tea; and he valued highly some extract of tea supplied him by Dr. Bence Jones, of which they were able to make a warm infusion when the heat of the lamp was insufficient to boil water. He had suggested this extract for use in the Nares expedition, but his suggestion was not acted on. He travelled with two or three of his men about twenty miles a day, on one occasion twenty-four miles. He did not claim great credit for this. He and his men were accustomed to sledging, were able to kill game, reindeer, etc. The meat was chopped up fine and mixed with the animal's blood, which was preserved frozen in the stomach. Certainly they had not half the quantity of meat that the Leigh Smith expedition had; and perhaps if the *Eira* had been wrecked fifty miles away they might not have found any walrus. Again, the men of the *Eira* were all whalers and sailors, and yet were not under naval discipline. So in his own case; there were no officers, but he never had a word with the men. He opened a school and taught them. They first had to get food, which they risked their lives in procuring. His books placed against the wall froze together, and could be only thawed by taking them into their beds. In spite of this intense cold, etc.,

there was no scurvy. They had no lime-juice and hardly any vegetables. He was not afraid at all that scurvy would break out if men were given plenty of exercise and not kept too warm in winter. A great quantity of meat seemed necessary, about 8 lb. per man a day. Sir J. Richardson calculated that his men's ration was from 7½ to 7¾ lb. The reason why so much meat is needed is perhaps because the system requires something that is present in meat in but small amount. His own experience of scurvy was when he went to Hudson's Bay forty-nine years ago, as a newly qualified surgeon of twenty years of age. Scurvy broke out, and they had only a scanty supply of lime-juice, salt junk, and barely any vegetables. The men fell ill one after another; the captain and first mate died, both of them being rather addicted to taking too much grog. As the spring advanced, the snow cleared off a hill near them, and a bed of cranberries was disclosed. He turned the scorbutic men to feed on these cranberries, and before the ship was ready for sea they had all recovered. There was also some wild vetch, with which they made soup. He agreed that people can live without vegetables, provided they have fresh food; and he had always recommended that cranberries should be taken on Arctic expeditions, for he believed they contained substances most likely to drive away scurvy.

Sir W. Smart had listened with great pleasure not only to the papers that had been read, but to the statements of those who had had experience of the disease. Although as a naval officer, it had been his duty to acquaint himself with the literature of the subject, he had never seen scurvy except on the coast of Africa and in the Crimea. For, although he had charge of Haslar Hospital for four years and a half, he had never seen a case of scurvy there. An animal diet is of the highest importance in the prevention and treatment of scurvy. He had read in Churchill's voyages how eight Englishmen in 1630 were left without food on the coast of Greenland in the month of July. They remained there till the following May, having no vegetables, but subsisting on the animals they could kill. When rescued, in May, 1631, not one of those men had a symptom of scurvy. In Kane's expedition, where the men passed a winter upon the ice, no scurvy broke out; their food being composed of the animals they killed. It was not necessary to cite other instances after Dr. Rae's testimony on this point. He could only say that an animal diet would suffice for six months to ward off scurvy as well as a vegetable diet could. The men of the *Investigator*, although shut up for two winters and three summers, did not begin to suffer from scurvy until the third summer. They had been able to obtain animal food—reindeer, musk ox, and ptarmigan—in great abundance, and had subsisted on it. But in the second spring they began to find they would not get out for another year, and with the warm weather scurvy appeared. This instance showed that an animal diet was preventive of scurvy up to a certain point; moreover, mental despondency was added to the causes of the disease from which more than one died after the rescue. Sir John Ross in 1830-33 obtained a good deal of fish as well as animal food, and the amount of scurvy amongst his men was very small. The valuable and interesting paper by Mr. Neale not only raised the question of animal diet being antiscorbutic, but it proved the advantage of living in huts, rather than on ship-board. He believed that men are kept too warm when confined to the ships, and that the heat and moisture are harmful. Parry in one of his voyages says that he considered damp and heat the principal causes of scurvy. Ross showed that

in his hut men could bear a very low temperature, and Dr. Rae and Mr. Neale had borne this out in their experience. Therefore he believed that the prevailing system of making the ships a kind of hot stove in the Arctic climates is a great mistake. Dr. Colan had told them what was the state of things on board the *Alert*, and he (Sir W. Smart) had always maintained that this was the reason why the men who went on the sledging expedition returned to the ship in a worse state of scurvy than if they had lived in a hut. The use of antiscorbutics was the only rational means of preventing or curing the disease; and if scurvy breaks out on board ship, if fresh meat or vegetables cannot be obtained, then lime-juice should be given; vegetables, of course, could not be got at the North Pole. During 150 years the importance of lime-juice had been fully proved. Vegetable food alone was not sufficient; scurvy broke out in a French vessel laden with citrons. Dr. Colan's suggestion that a shipload of sheep should be sent with every expedition was valuable; but why was not time for ships to stop in Smith's Sound allowed to permit of a sufficient supply of fresh meat being stored?—Dr. De Chaumont said that he had no experience of scurvy in the Arctic regions, but had met with it in the Crimea and in civil life. Mr. Neale's paper and Dr. Rae's remarks were very valuable as showing the importance of a diet of fresh meat. In the Crimea, in the spring of 1856, the men were left on one occasion fourteen days without fresh meat, and scurvy began to appear among them. There was a tolerable supply of vegetables, chiefly dried potatoes; and officers, on paying large sums (as 2s. 6d. for a cabbage, and £4 for a small sack of potatoes), could get fresh vegetables. The fact was that the commissariat, having salt rations on hand, kept the men on these, although there were 10,000 cattle eating their heads off in the neighboring plain. The want of fresh meat was then a cause of scurvy. His opinion as to the disease had not been altered by what he had heard that night. It was 'a disease of the blood due to deficiency of organic acids and salts, and the reason why lime-juice and fresh vegetables were of value was because they contained these substances in the largest and most concentrated form. If the *Eira* Expedition had lived entirely on walrus meat, it would have been a crucial test of the efficacy of such a diet; but they also had a very large quantity of vegetables, nearly half a pound daily for the fifty weeks. Affairs were very different in the Nares' Expedition, the crews there were under bad hygienic conditions; they had a large quantity of vegetable food, pressed potatoes, pickles, jam, lime-juice. Indeed, Captain Nares gave his men a double allowance of lime-juice, thinking it would the better ward off the scurvy; but he did not consult his medical officer on the point, or as to the victualling of the sledging parties—viz., one pound of pemmican, no lime-juice, and two ounces of dried potato. It had been said that dried potato was equivalent to five times its quantity of the fresh tuber, but this was an error. There was no wonder that the men knocked up on this ration, particularly when the work they did was considered. On the most moderate computation, he had calculated that each man on one of these sledging expeditions did work equivalent to 500 foot-tons per diem. For a well-fed, healthy man 300 foot-tons is a good day's work; and it must also be remembered that the men on the expedition were often unable to swallow their pemmican, and were exhausted by diarrhoea. The conditions, therefore, of the two expeditions were totally different. The damp and foul air on board ship must be put aside as a cause, for the men did not get the scurvy till they went on the sledging expedi-

tion. A main cause of the outbreak of scurvy among the crew of the *Investigator*, referred to by Sir W. Smart, was that the supply of lime-juice failed them. It was probably the lactic acid in fresh meat that gave it antiscorbutic qualities, which was further supported by Dr. Rae's remarks as to the large quantities of meat that the men required. It would be suicidal of any government to equip an expedition without fresh vegetables or lime-juice. Dr. Rae told him that in one of his expeditions he had found fresh fish of service, as salmon. As to the supposed immunity of the Esquimaux, it must be remembered that they freeze and store up for consumption all the vegetable matter found in the stomachs of the reindeer and musk ox. The Kafirs are in the habit of eating the contents of the stomach of oxen, no doubt with the same object. In the Cape scurvy has broken out at times amongst our soldiers, although it is a warm climate, but where no vegetable food was at hand. Then there are cases in civil life among people who neglect eating vegetable food; they have scorbutic symptoms, which are cured by lime-juice. Dr. Aitken had told him that one of the worst cases he had seen was in civil life; the patient had been living almost entirely on roast mutton and bread. He was cured by vegetables. Dr. De Chaumont thought that it would be very dangerous to apply the results obtained from the *Eira* Expedition under favorable circumstances to all circumstances. In some cases of scurvy vegetables have been used more or less, but until we can get freedom from scurvy in cases where diet is restricted entirely to meat, the view of the influence of vegetables cannot be discovered. But it must not be supposed that all those who are placed under conditions liable to produce scurvy will get it. Some people are exempt from typhus fever, although exposed to infection. There may be found in picked crews men who are capable of withstanding the evil influences which produce scurvy.—Sir Joseph Fayrer pointed out the enormous decrease in cases of scurvy admitted into the Naval Hospital on the introduction of lime-juice at the close of the last century; before then there were 2,000 cases in the fleet; but after the introduction only one man a year. He remembered the intense desire for vegetable food he and his companions experienced when shut up in Lucknow during the siege. Men risked their lives to obtain the small species of cruciferous plant that grew outside the walls, which were sold to the besieged residents for its weight in silver. Scurvy attacked many of them, who (he among them) had to be sent home. The hygienic conditions under which they had lived during these five months had been very bad, and these coupled with the utter absence of vegetable food, produced scurvy. At the same time people do get scurvy although having vegetable food, as he had seen in malarious districts in India cases presenting all the features of scurvy, in the condition of the gums, hemorrhages beneath the skin, and in the sheaths of tendons.

Dr. Robert Barnes had some experience of scurvy as physician to the *Dreadnought*, and had spent a year on board a merchant ship. He concluded that the absence of lime-juice, as representative of food containing the essential salts for healthy nutrition, was the cause of scurvy. Other substances possessed the same properties. Men and women had lived for a considerable time on a floe of ice, subsisting on raw flesh, which might be likened to milk. Dr. Rae's experience bore this out. At the same time vegetables will largely supplement animal diet. If a government could be found which would send out an expedition to the Pole without supplying lime-juice, or its equivalent, it ought to

be indicted before the opinion of the world. In merchant ships scurvy is a disease of the fore-castle, not of the cabin. If the captain and his officers can take care of themselves as to diet, he should be bound to look after his men too. There should be an inspection, not of the food alone, but of the crew, and the captain should be held as responsible for their health as the master of a household is for those under his care. It had been conclusively shown that night that raw meat and blood were admirable adjuncts to lime-juice as antiscorbutics. Although bad hygiene has some influence, it must be remembered that scurvy has broken out in the open air—in Canada, in the tropics, and elsewhere.—Dr. Rae, referring to Dr. Barnes's remark, mentioned that of the twenty-nine deaths in Franklin's ships nine were officers.

Dr. Barnes said he was alluding to the merchant service; he was aware that in the Army and Navy officers always endure privations with their men.

Dr. Buzzard said that even if he had not recorded his convictions about scurvy in an article he wrote in Reynold's "System of Medicine," fifteen years ago, he should have felt it unnecessary to say anything after the speeches they had heard from Drs. DeChaumont and Barnes. He wished, however, to ask Mr. Neale a question: Did Mr. Leigh Smith suffer from scurvy?—Mr. Neale: Not in the slightest degree.—Dr. Buzzard: Then, did Mr. Leigh Smith eat any of the fresh meat?—Mr. Neale: No; Mr. Leigh Smith only partook of the soup, but always insisted on his portion being well thickened with blood. He was unable to eat the coarse animal food.—Dr. Buzzard continued, pointing out that the pressed potatoes are only half boiled, and are not dried or submitted to prolonged heat, which might affect their antiscorbutic value; and no less than half a pound of these pressed vegetables was available for each man of the *Eira* during their sojourn.—Dr. Reginald Thompson said that as a little doubt had been raised as to the possibility of a man living on an exclusively meat diet, he would mention that when he met Dr. Rae in Rupert's Land he was in charge of an expedition of half-bred natives. They had no vegetables, but some tea, sugar, and flour. He was never in better health, and ate enormously of meat, which, on the only two occasions he had an opportunity of employing it, amounted to 8 lb. a day. This supported Dr. Rae's remark that if one has to subsist on a meat diet enormous quantities have to be taken.—Mr. Neale, in reply, suggested that Dr. Colan should have made use of the acids, of which they had such abundance. The vegetable supply on the *Eira* was not more than other expeditions had. These men were subjected to fatigue. Dr. Rae and Sir W. Smart had given instances of the value of fresh meat. The failure of a meat diet in summer, as in the *Investigator* case, might be explained chemically by changes which the flesh underwent after being killed. It was very important that the meat should be quite fresh, and the blood unchanged. The crew of the *Eira* were not picked men. They were collected from Peterhead and Dundee after the whalers had left. Some of these men had had scurvy, when kept on board ship on previous voyages. One of these, who had had scurvy three times, on one occasion was so bad that he was sent on shore to die; but he was put between two Esquimaux women and had flesh diet, and recovered. Captain Murray, of Peterhead, had wintered in the Arctic regions eleven or twelve times, but had never had scurvy, living on seal meat. He did not wish to say for a moment that vegetables and lime-juice do not act as cures for scurvy, but to suggest that fresh meat would be found equally efficacious.

The President apologized to Dr. Hale White for

not calling for a discussion on his paper, but there would be an opportunity for his observations to be dealt with at a future meeting, when two other papers dealing with the pathological aspect of scurvy were to be read. He thanked the writers who had contributed so much that was interesting. Hitherto scurvy has been dealt with on empirical principles; none of the trials made were scientific, they all contained fallacies, such as Dr. DeChamont had indicated. If any Government inquiry were instituted it ought to be a scientific inquiry, and they should first have scientists to tell them what scurvy is, and then inquire as to its rational treatment. This was one of the cases where English medicine was on its trial, and he trusted that the subject would now receive full and complete scientific investigation.

Annual Meeting.—President's Address.

The annual general meeting of the Society was held on Thursday, March 1st, 1883, Mr. John Marshall, F.R.S., President, in the chair.

The President, on taking the chair, declared the ballot open for one hour, nominating Dr. C. H. Carter and Mr. George Eastes as scrutineers. The report of the President and Council, which was read by the Secretary (Mr. Berkeley Hill), announced to the meeting the continued prosperity of the Society, and the progressive increase in the number of its Fellows. The number of deaths among them had been nineteen, which was about the average of the last twelve years, and among these were two of the honorary Fellows, Mr. Charles Darwin and Dr. John W. Draper. The new elections had been twenty-six (twenty-one resident and five non-resident). A few minor changes among the Fellows as to non-residency, etc., were enumerated, and the number of subscriptions was stated to be 301, against 292 in the last report, and the total number of the Society, resident, non-resident and honorary, was 704. The items of receipt and expenditure were, in most cases, much the same as in recent years, an increase, however, being observable in the expenditure on the library, stationery, and repairs account. There had been also a large "extraordinary" expenditure on repairs of the exterior of the house, which the ground landlord had required to be done, and which, with an expenditure on the seats of the meeting and other decorative improvements, amounting in all to about £250, had been defrayed, with the exception of a small balance, out of the current receipts of the last two years. It was stated that these alterations, much to the Society's benefit, had been carried out with great judgment and economy under the careful supervision of the retiring secretary, Dr. Reginald Thompson. The payment of the sum of fifty guineas to the Harvey Tercentenary Memorial, voted at previous anniversary meetings, having been shown to be illegal, the amount had, owing specially to the exertions of the treasurer, Mr. Cooper Forster, been made up by a subscription among forty of the Fellows. The report also alluded to the time having arrived for a second award of the Marshall Hall Memorial Prize, and that the Council recommended to the Society its presentation to Dr. David Ferrier for his investigations into the physiology and pathology of the nervous system. A change in the character of the printed proceedings had been made by the introduction of reports of the discussions at the meetings, and, to facilitate these discussions, abstracts of the papers had been printed for distribution before each meeting. The report of the librarians stated the number of additions to the library (467 works), and, after referring to the triennial inspection of the library by the committee having taken place, and

the library found in excellent condition and perfect working order, gave full details as to the number of volumes in the library (33,500), the number of books taken out, of daily visitors, etc. The adoption of the report was moved by Dr. Julius Althaus, who congratulated the Society on its prosperous condition, and praised in eloquent terms, and with reference to the contemporary condition of scientific research on the nervous system on the Continent, the judicious award of the Marshall Hall Prize to Dr. Ferrier, whose researches rendered him so worthy a recipient of it. The motion was seconded by Mr. Pickering Pick, and carried unanimously. The President then called upon Dr. David Ferrier to come forward, and addressing to him a few complimentary words upon the grounds upon which the award had been made to him, presented him with the diploma recording his selection as the second Marshall Hall prize-man, and with a cheque for the amount of the prize (£85) at the same time. Dr. Ferrier thanked the President and the Society for the high honor they had conferred upon him by their selection of him as a recipient of the prize.

The President in addressing the meeting introduced at once the subject of the losses the Society had sustained among its Fellows during the past year, which he said were so numerous and important that he must defer the task of considering more general questions relating to the Society and to the progress of medicine and surgery to a future opportunity. The President gave a short classified enumeration of the deceased Fellows, of whom the non-resident were nine, including three, Drs. F. E. C. Hood, F. R. Hogg, and Charles Morehead, who had served with the army in India; three others, Drs. Richard Elliot, of Carlisle, Richard Cross, of Scarborough, and William McEwen, of Chester, who had been engaged in practice in large provincial towns; and three, Drs. W. W. Johnson, Joseph Williams, and George Budd, who had retired from metropolitan practice to reside in the country; one deceased physician, Sir James Alderson, though he had ceased to belong to the Society, was connected with it for many years, partly as a non-resident, but chiefly as a resident Fellow, and had in 1865-6 been a President of the Society. There were eight deceased resident Fellows, Dr. Robert W. Lyell, Dr. Alexander Silver, Mr. J. T. Clover, Dr. Robert Taylor, Mr. George Critchett, Dr. Peacock, and Sir Thomas Watson; and there were two honorary Fellows, Dr. John William Draper, of New York, and Mr. Charles Darwin. The President went into full details of the lives of the deceased, taking the individuals in each class in the order of the duration of their fellowship, beginning with the youngest, which he said he found to correspond with their ages, influence, and position in the profession. For such statements, he said, as were not based on his acquaintance with the deceased, or on circumstances regarding them which had come within his own cognizance, he was much indebted to obituaries which had already appeared in the public journals.

In his notice of Dr. George Budd, the President referred to the interesting fact of so many of his brothers (seven out of nine) having become members of the medical profession, he being third wrangler at Cambridge, and his successive connections with the Middlesex Hospital, the *Dreadnought* Hospital Ship, and King's College, the offices he held at the College of Physicians, and the production of his standard work on Diseases of the Liver and Stomach. In the notice of Mr. Clover, he went very fully into the points of the amiability and unselfishness of his character, his patience and cheerful resignation under the wearing effects of chronic pulmonary disease; and his large expe-

rience and wonderful ability in the administration of anesthetics, so well illustrated in his valuable article on the subject in Quain's "Dictionary of Medicine." Full notices of the life-incidents, character, and works of Mr. George Critchett, Dr. T. B. Peacock, and Sir Thomas Watson, concluded the obituary portion of the address, in which the speaker largely dwelt upon Mr. Critchett's excellence as a teacher and his acknowledged dexterity as an operator, his promptness in consultation, and considerate kindness to his patients; Dr. Peacock's predilection for pathological investigations, and his gradual concentration of them on the malformations and diseases of the heart; the presentation of his unrivalled collection of examples of these diseases to the Hunterian Museum; his strongly marked individuality, precision, conscientiousness, and simplicity of character; and his fondness for foreign travel and frequent journeys abroad for the recuperation of his energy. The origin, and collegiate, and early life of Sir Thomas Watson, the "Nestor of English Medicine," who had died at the patriarchal age of ninety years and nine months; his connections as physician and lecturer with the Middlesex and King's College Hospitals and their outcome in the publication of his celebrated Lectures, the estimation of which has been in our time almost unique, the description of disease in them being so full and clear as to cause him to be compared with Sydenham, and their scholarly style having gained for him the appellation of the Cicero of English medical literature; his professional eminence, moral worth, sagacity, integrity, and steady adherence to those high principles of duty which made him so fit to advise on all ethical questions relating to our profession, entitled him justly to the name of the "greatest English physician of the present century." The President then gave biographies of the two Honorary Fellows: Dr. James William Draper, the physicist, chemist, and physiologist, and Charles Darwin, the great naturalist; with notices of their works, and a discussion of the question of the important influence they had had, especially those of the latter, on the science of the day; and then summed up his address with reflections on the lessons we might derive from these histories of the careers of the deceased members, from which peroration the following words are extracted:—"The thought has often occurred to me, and no doubt to many besides, what an amount of accumulated experience and wisdom is blotted out at the death of each master of the craft of medicine and surgery; and if we reflect on the number of gifted, learned, and industrious men who have passed from our ranks during the last twelve months, we may well feel dismay that so much slowly acquired individual knowledge has been here extinguished, and so much personal power has thus died out. But, fortunately, owing to the liberal intercommunication of ideas which distinguishes the real from the false disciples of Esculapius, amongst the instruments of which are societies or brotherhoods like ours, such knowledge and power are handed on from period to period, and the example of one generation is emulated by its successors. If we study the record of the lives of our deceased Fellows which I have put before you, we find that they possess one common characteristic—viz., devotion to work. Whether they were born to affluence, or entered upon life supported by moderate or scanty resources; whether their early education was of the highest order, or of humbler pretensions provided for them or secured with difficulty; at whatever medical school they were trained; whatever professional titles they acquired; whatever the branch of practice to which they had recourse; whether in Lon-

don, the provinces, or abroad; whether they had the early support of powerful friends, or struggled upward by themselves; whether they were shaped by circumstance or compelled circumstances to bend to them; whether they aimed solely at professional eminence or sought relief to their redundant energy in the duties of citizens besides; whether they were rewarded by the rich or the poor, by the public, the profession, the Government, or the Crown; and, lastly, whether their lives were so prolonged as to secure the full fruition of their aims, or were cut so short that they saw but visions of future success—it is apparent, I say, that all were devoted to their work." After a few words relative to the special interests of the Society in relation to the deceased Fellows, the President concluded by exhorting the Fellows to continued efforts towards increasing the prosperity of the Society.

A vote of thanks to the President for his address was moved by Mr. Spencer Wells, and seconded by Mr. H. W. Page; and the motion, having been put to the meeting by the Treasurer (Mr. Cooper Forster), was carried with acclamation. Thanks were also voted, on the motion of Mr. Thomas Smith, seconded by Dr. Macfarlane (of Kilmarnock), and carried unanimously, to the retiring vice-presidents and other members of the Council; and a vote was also moved by Mr. Christopher Heath, seconded by Mr. R. W. Parker, and carried with applause, to the retiring secretary, Dr. Reginald Thompson, and the retiring librarian, Dr. Edward H. Sieveking, for their zealous and valuable services, the mover especially referring to the rather severe addition to the usual secretarial duties which had fallen to the lot of the retiring secretary, who, during the three years of his holding office, had had to superintend repairs, alterations, and improvements, external and internal, of the Society's premises, in which his valuable knowledge and judgment in these matters had been of the utmost service to the Society.

During the course of the meeting, the President announced the result of the ballot for officers and council for 1883-84:—President: Mr. John Marshall. Vice-Presidents: Dr. John Russell Reynolds, Dr. Reginald Edward Thompson, Mr. William Scovell Savory, Mr. Richard Barwell. Treasurers: Dr. Charles Bland Radcliffe, Mr. John Cooper Forster. Secretaries: Dr. Reginald Southey, Mr. M. Berkeley Hill. Librarians: Dr. Charles Hilton Fagge, Mr. John Whitaker Hulke. Other Members of Council: Drs. G. F. Blandford, Dyce Duckworth, Gee, Pavy, J. E. Pollock, and Messrs. Cowell, Henry Power, Howard Marsh, Septimus W. Sibley, and Spencer Watson.

CLINICAL SOCIETY OF LONDON.

Hydrophobia.—Pseudo-hypertrophic Paralysis.

THE ordinary meeting of the Clinical Society of London was held on Friday, Feb. 23rd, Dr. Andrew Clark in the chair. In reference to Dr. Broadbent's cases of true and spurious hydrophobia, we are requested to state that the committee appointed by the British Medical Association to investigate this disease is still continuing its investigations, and the members of it would be glad to have the opportunity of themselves examining any cases of this disease.

Dr. Broadbent's first case was one of supposed Hydrophobia, treated by Chloral; recovery. The patient, a boy, aged twelve or thirteen, was admitted into St. Mary's Hospital on Feb. 20th, 1876, suffering from violent convulsive attacks, which had been going on for two days. The paroxysms

were ushered in by a loud, deep breath, and there was first momentary rigid extension of the body, followed by rapid rotary movements of the head, with loud laryngeal sounds, which lasted two or three minutes, after which the boy moaned and complained of pain in the head. These attacks were at once brought on by an attempt to drink, by the sight or sound of falling water, by the contact of a cold object, or pressure over the heart, or by light thrown into the eye in attempts at ophthalmoscopic examination. In the intervals the boy was conscious and fairly clear in intellect; his countenance was pale and anxious; the skin clammy; temperature normal; pulse 108, small, weak, and hesitating; respiration sighing. There were frequent extensive jerks of the body and limbs. The idea of hydrophobia had occurred to his parents, but the only dog the boy was known to have played with was alive and well. When asked if he had ever played with a strange dog, the boy said that he and some companions had found and shut up a strange dog, and that it had bitten him on the hand, but he had forgotten which. There was found, however, on the fleshy part, between the thumb and finger of the right hand, a small scar, surrounded by an extensive induration like that of a chancre. After a trial of nitrite of amyl, with no good effect, twenty grains of chloral, one ounce of brandy, and two ounces of beef jelly, were given by the bowel every three hours. The boy slept, had only slight occasional spasms, and was soon able to drink milk. On the 28th he was apparently well, and the chloral was suspended; but on the evening of the 29th he had a violent relapse, which continued. On March 1st chloral was again given till the 11th, when he had been up and running about the wards for several days. He remained in the hospital till April 2nd, and was kept under observation for some time longer. When he was taken to the hospital chapel, the first notes of the organ threw him into a state of uncontrollable excitement, with violent throwing about of the arms; and he could not for a time bear the sound of a barrel-organ. The case was submitted to the Society exactly as it was written out six years before from the notes of Mr. Jackson Garritt, at that time resident medical officer. If the boy had died there would have been no doubt of the disease being ascribed to hydrophobia. The symptoms, while not corresponding in all particulars with those seen in some fatal cases, were closely similar, and the induration round the bite was corroborative evidence. The circumstances excluded emotional excitement as a cause of spurious hydrophobia; and there was nothing in the boy's previous history or character to suggest that he was a likely subject for hystero-epileptic simulation of the disease. Chloral was given, partly because it seemed best adapted, from its physiological effect, to relieve the spasm, partly in the hope that it might rob death from such a disease of part of its horrors.—Case 2: A healthy girl, a month after being bitten by a strange cat, complained of nausea, sickness, and loss of power in the arms, and next day, after feverishness and thirst, became excited and unmanageable, and was brought to the hospital at 10 p.m., July 31st, 1881. She was excited and delirious, but could answer questions; asked for water, though she could only take it out of a spoon after hesitating and with evident effort; it was swallowed with difficulty and provoked spasm of pharynx and neck. Chloral and bromide of potassium were given in beef-tea by the rectum. During the night the child became rapidly worse, more delirious and excited, with expectoration of viscid mucus and complete inability to swallow. She died exhausted less than twelve

hours after admission. At the post-mortem examination there was some congestion of the brain and upper part of the spinal cord, especially in the floor of the fourth ventricle, and sections of cerebral cortex and all other parts showed congestion of vessels, and a few punctate extravasations into the perivascular spaces but no cellular infiltration.

Case 3 was one of pseudo-hydrophobia. A man aged twenty-six, who had gone through much excitement and anxiety, which had led to more or less alcoholic excess, five years after being bitten by a dog was suddenly seized with choking while drinking spirits after giving evidence in a court of law. Apparently some of the liquid got into the larynx. He was seized with panic that he was going mad. After three days of excitement and sleeplessness he was brought to St. Mary's Hospital, on Oct. 25th, 1876, about 10 a.m., in a wild and anxious condition, dreading the approach of liquids, and on any attempt to swallow them seized with spasms of the pharynx and neck, and gasping for breath. He swallowed solids. He could be quieted by firmness, but soon relapsed. He hawked, spat, and pulled at his throat. During the evening, after removal to an isolation ward, he was quieter, and could drink liquids. In the night he slept at times; but at others he was noisy, and he tried to strangle himself, and to get out of the window. On the morning of the 26th he was calmer. Through the day his condition varied; but at 4 p.m. he was rational and tranquil, and took bread-and-milk. Soon after this the visit of his wife and child brought on a paroxysm of greater and more violent excitement. In the evening he was put under chloroform, and could then both breathe and swallow. The excitement, however, returned, and was followed by exhaustion, and he died about 10.45 p.m. At the post-mortem examination, fifteen hours afterwards, the rigor mortis was very great. All the internal organs, but especially the lungs and kidneys, were congested. The membranes, cortex, and white substance of the brain, pons, and medulla were greatly congested, as was also the spinal cord.—Case 4: The patient, a boy aged thirteen years and a half, was admitted on Jan. 18th, 1883. He had been bitten by a puppy five months previously on the finger; the wound was cauterized within five minutes, and twice subsequently. The dog was confined, and a week later killed, because it was then thought to be going mad; the boy constantly talked about hydrophobia. On Jan. 15th he had pain in his back, but up to the 17th had only symptoms of a bad cold. On January 18th he could not swallow liquids or suck an orange; spasms were induced by the attempt. There was an excessive flow of saliva, with foaming at the mouth. He started up at times, saying he could not breathe, and was excited. On admission the prominent symptom was emotional excitement. He would not allow liquids to be brought near him; the abdomen was retracted and hard, and the face flushed and wild. Pulse frequent; temperature 100°. An enema of gruel and castor oil was ordered, and after this an enema of beef jelly, half an ounce of brandy, and twenty grains of chloral, every three hours. Three hours later he asked for, and tried to drink, milk; it was with much difficulty that he got the spout of the feeding cup to his mouth, and when he did so the fluid provoked a most violent spasm of the neck and arms and great respiratory distress. He afterwards, however, sucked an acid drop, and swallowed the saliva. Respiration was irregular and jerky (36), much moaning and whining, pain and tenderness at the epigastrium. The gruel and castor oil did not return, and the beef tea and chloral had to be given upon it at seven o'clock. During the even

ing and night the patient became more and more excited and violent; the respiration was rapid, catching, oppressed; the pulse extremely frequent, perspiration pouring off the face, at times convulsive paroxysms of neck and arms. At 11 p.m., after a second enema of chloral, brandy, and beef-tea, he was so violent that restraint by bandages, etc., was necessary. At 2.45 a.m. twenty grains of chloral were given hypodermically, and the patient slept three hours. At 10 a.m. of the 19th he was quiet, listless, and drowsy, but contact of the hand or turning down the bedclothes caused a long deep inspiration. He made no complaint of pain. Respiration more even; pulse 130, small and weak; temperature 101°. At 11 a.m. the urine had to be withdrawn by a catheter, the amount was sixteen ounces, the sp. gr. 1030, no albumen or sugar, but urates thrown down on cooling. After this the spasms were slight and infrequent, but the exhaustion increased; there was much foaming at the mouth; the temperature remained at about the same point. Sordes formed on the teeth. The patient died at 10.25 a.m. on the 20th, about forty-three hours after admission. The administration of chloral was suspended when the spasms ceased, beef-tea and brandy being given. At the necropsy three hours after death, the rigor mortis was extremely pronounced; the cerebral meninges, cortex, and white centres were extremely congested; puncta cruenta, too, numerous and large, membranes over pons and bulb slightly congested. No excess of serum in ventricles. Nothing noteworthy in chest or abdomen except two living round worms in small intestine just above the valve.—Dr. Clark asked if the urine of the first boy was examined.—Mr. Broadbent replied that it was often examined and always found normal.

Dr. Dyce Duckworth thought that in all particulars the first case resembled cases of hydrophobia, and he could not doubt that it was that disease. He referred to a case he had treated in which life was certainly prolonged for some days by chloral. He thought that chloral was as useful as any other remedy in hydrophobia. The mode of action of chloral suggested its value; it should always be given with nutrient enemata. With reference to spurious hydrophobia, he said that if the patient be very gently blown upon, and the effect watched, it greatly aided the diagnosis, for the slightest stream of air induced severe paroxysms in the true hydrophobia and not in the false; he thought that chloral, at any rate, gave time during which the poison might be eliminated.—Mr. Pick did not think the first case was certainly one of true hydrophobia. There generally appeared to be some premonitory symptoms, one of which was an aching pain about the wound; this was absent in Dr. Broadbent's case, and there was malaise with a sense of impending evil, and when the attack came on there was between the paroxysms excessive mental terror; these also were absent in Dr. Broadbent's case. He therefore could not speak with confidence of the diagnosis.—Dr. Whigham asked whether the spasm in the neck was always present in human hydrophobia. In neither of three cases in animals which he had seen was there any spasm in the neck excited by the sight of water. One was in a sow, another in a dog which tried to drink from a pond, and there was no spasm whatever, the third was also in a dog which tried to eat some bread-and-milk, but there was no spasm of the glottis or of the muscles of the neck.—Dr. Ewart thought Dr. Broadbent's cases were very valuable, even if the disease were spurious. Hydrophobia was quite a misnomer as applied to animals. If there was a specific virus at all, what was rabies in the dog was rabies in the man. If rabies were true hydrophobia, what was false hydrophobia? What

were the cases in which the symptoms were exactly the same? One set of cases might show special pathological changes and the other not; but we yet lacked a proof that the transmitted virus actually produced the cell infiltration in every case. The test of the incurability of true hydrophobia was unworthy of this age of medicine. The dog communicating a fatal attack might himself recover.—Dr. Longhurst asked the total amount of chloral given in the first case, as it was a very powerful remedy, and the pathological changes might have been caused by the chloral.—Dr. Clark asked Dr. Broadbent to state exactly what led him to call the first true and the two latter false hydrophobia. The age of the first boy was one liable to *bizarre* nervous conditions, as intense excitement.—Dr. Mahomed asked if it was not incumbent upon all physicians meeting such cases to try the effect of inoculation in lower animals.—Dr. Clark said that the law did not permit of this.—Dr. Duckworth said that at St. Bartholomew's Hospital Dr. Brunton had practiced inoculation in their last case, and had obtained no result. They therefore had abandoned the experiment.—Dr. Broadbent quite agreed that there ought to be a distinct name for rabies and similar diseases arising from other causes than rabies. The evidence of specific inoculation, and the presence of an indurated painful scar, enabled him to make the diagnosis. In the two spurious cases there was a history of great previous excitement, such as would lead to the paroxysms. But in the first boy there was an entire absence of any such condition. The last boy had 220 grains of chloral altogether; it was suspended for the last twelve or fifteen hours before death. He had not added up the total in the case of the boy who recovered.

Dr. J. Kingston Fowler exhibited two cases of Pseudo-hypertrophic Paralysis in adults of the same family, and read notes of their cases. Case 1: H. F.—, aged forty-four, a blacksmith's striker, married, ten children. A careful examination of the family history, and especially of the collaterals of the parents showed that no instances of the disease had occurred amongst them for at least three generations. The patient had had three attacks of acute rheumatism. When a young man he was remarkably strong. The first symptom of the disease, a peculiar swaggering gait, was noticed at the age of twenty-eight. This was followed six years later by a considerable loss of strength and weight. At the age of thirty-six he began to experience a sense of fatigue in the legs on over-exertion and a difficulty in mounting a flight of steps. He frequently fell down whilst at work, and when on the ground had much difficulty in rising again. He continued at work until 1879, when he was admitted into Middlesex Hospital under Dr. Cayley, and his calves then presented considerable enlargement, whilst the biceps and pectoral muscles were wasted. The patient was a healthy and cheerful-looking man of medium height. Intelligence was normal, and there was no affection of special or tactile sensibility. The sterno-costal portions of the pectorals, the biceps, rhomboidei, serrati, latissimi, and erectores spinae were wasted. The triceps, the muscles forming the thenar and hypothenar eminences, the dorsal interossei and the external vasti and calf muscles were large and firm. There was no marked talipes equinus; the enlarged muscles generally were weak; the head and shoulders were thrown backwards. There was well-marked lordosis of the spine, disappearing on sitting down, the latter movement being accomplished with difficulty. When placed on his back he was unable to turn over or to resume the erect position. His attempts to do so

were characteristic of the affection as seen in children. The patient had kept records of the circumference of his right arm and calf from the age of eighteen; these compared with the present measurements showed a diminution of four and a half inches in the girth of the former, and two inches in that of the latter. The electrical reactions, ascertained by Dr. Hughes-Bennett, were normal with faradism to the nerve trunks and to most of the muscles; the responses from the affected muscles were much diminished. Galvanism to the nerve trunks gave normal reactions, and also to most of the muscles, but with increased A.C.C. To the affected muscles the contractions were much diminished in quantity and altered in quality the A.C.C.—C.C.C. The knee-jerk was absent. The temperature of the skin over the atrophied muscles was about 1° higher than over the enlarged muscles. Iron, quinine, strychnine, and cod-liver oil had been given without much benefit resulting. Improvement had been observed under arsenic and faradism. Case 3: R. F—, aged thirty, brother of the first patient following a similar occupation. In this patient the disease was in a much earlier stage; nearly all movements could be performed without difficulty, but muscular power was weak. At the age of twenty-seven he was noticed to have a difficulty in ascending a flight of steps, using the banisters to pull himself up. At the same time the arms and legs began to waste. The patient was a slightly built man, intelligent, and free from any obvious disorder. The sterno-costal portions of the pectorals, the latissimi, serrati, rhomboidei, teres, and biceps muscles were wasted; the triceps, infra-spinati, external vasti, and muscles of the calf were enlarged and hard. This patient had also kept records of the girth of his right arm over the contracted biceps, and also of his calves, from the age of twenty-one; a comparison of these measurements with those taken recently showed a diminution. This patient had not been under medical treatment. The opinion was expressed that these were cases of the same affection seen not unfrequently in children, and first named by Duchenne pseudo-hypertrophic paralysis. Reference was made to similar cases of this disease as it appears in adults recorded by other observers. It was thought that these were the first cases recorded in which the disease had appeared at adult age in members of the same family.

Dr. Broadbent said the cases were very interesting, and were recorded with most praiseworthy accuracy. He had come to the opinion that the hypertrophy was an incident of age, in support of which he had alluded to two sisters in whom the disease came on between eighteen and twenty, and in whom the hypertrophy was much less than in children. This fact was also to be noted in Dr. Fowler's cases. He had seen a case coming on in a man about fifty. The disease was that of pseudo-hypertrophic paralysis in all its features except that there was scarcely any hypertrophy. Dr. Ross had described a similar case. He, therefore, thought the disease common in children prevailed also in later life, but that the hypertrophy was an accident of the active growth of childhood, while later the atrophy existed but was not masked by any hypertrophy in those of less active general nutrition.—Dr. Green said that the case he had recorded was twenty-two years old, and the disease followed an injury; the hypertrophy there was very considerable. He thought it was a question whether the wasting was not due to atrophy of the muscle tissue itself, which varied in different cases.—Dr. Ewart mentioned that he recently saw a case in which he was in doubt as to the diagnosis, because the patient was a woman aged thirty-five,

and there was no evidence of marked hypertrophy in any of the muscles; all the other symptoms were characteristic. He asked Dr. Fowler whether he had met with the records of the disease in any other adult females.—Dr. Clark thought it was important to call attention to the diseases of anatomical units and systems of organs of which this affection was a good example.—Mr. Fowler, in reply, stated that the disease was transmitted to males through females. The enlargement was chiefly due to the deposit of fat in the muscles. There was progressive atrophy preceding the hypertrophy.

Before the meeting Mr. Parker showed a child with Congenital Dislocation of the Hip Joints; and a case of obscure Lymphatic Affection of the Arm in a boy.

Excision of Ulna.—Necrosis of Roof of Orbit.—Picric Acid Test for Sugar.

The ordinary meeting of the above Society was held on March 9th, Dr. Andrew Clark, President, in the chair. Before the meeting Dr. Dyce Duckworth showed a case of remarkable hardness of the ears, and a woman with rheumatic subcutaneous nodules. Dr. Stephen Mackenzie showed a case of subcutaneous nodules without any rheumatic history. Mr. Godlee read an important paper, and Dr. G. Johnson demonstrated his mode of using picric acid as a qualitative and quantitative test for sugar.

Mr. R. J. Godlee related a case of Fracture of the Radius and Dislocation forwards of the Ulna at the Wrist, in which the lower end of the latter bone was removed to effect reduction. The patient, who was aged twenty, was jumping a high jump at a gymnasium when his feet slipped forwards on a badly secured mat, and the whole weight of his body fell suddenly on his hands, which were placed behind him. The left radius was fractured at the junction of the middle and lower thirds; the upper end of the fracture being compound, the lower end of the ulna was displaced forwards, and projected in front of the carpus beneath the skin. All attempts at reduction with and without an anæsthetic proved unsuccessful. An incision was made over the lower end of the ulna, and a hook was placed under the tendon of the flexor carpi ulnaris which had slipped behind the bone, but the bone could not be replaced until, first, the styloid process and then the lower end of the ulna had been sawn off. The wound was treated antiseptically, and healed without any inflammatory disturbance. In ten days it was placed in a plaster-of-Paris apparatus, and in about six weeks passive movement was commenced. The limb is now almost as useful as the other, and can be employed for gymnastic exercises as well as the ordinary uses of daily life; but pronation is not quite as free as before. The patient was shown at a previous meeting.—Mr. Clement Lucas had a somewhat similar case last autumn in a feeble old lady, who fractured the lower end of each radius by a fall on the hands. On one side, where the fracture was compound, the lower end of the ulna was also dislocated and fractured, but there was no difficulty in reducing it. Erysipelas and diffuse suppuration ensued, and amputation was performed, but death resulted. The lower end of the radius was in front of the upper fragment. He referred also to a case of excision of the lower end of the ulna, in which no adduction afterwards occurred, and suggested that this was because the radial muscles were stronger than the ulnar muscles. Excision of the lower part of the ulna was a good operation, as the wrist-joint was not opened.—Mr. C. Heath had a patient last year with a sinus over the end of the ulna; he

excised the end of the bone; the man recovered, with an extremely useful hand. He considered such an operation a great advance in modern surgery. He had seen Mr. Godlee's case, and thought it a most satisfactory one.—Mr. Godlee suggested that the explanation of the abduction of the wrist in cases of congenital absence of the radius, and of non-adduction after excision of the ulna, was that the carpus articulated much more with the radius than with the ulna.

Dr. Pearson, in conjunction with Dr. Broadbent, read an account of a case of Acute Necrosis of the Right Orbital Plate of the Frontal Bone, in a girl aged nine years and eight months. Four days after exposure to cold, symptoms of stiff neck, relaxed throat, causing restless nights, began, but so gradually that a medical man was not called in till the fourth day. When first seen the noticeable point in the case was that the child, when asked to sit up in bed, put both hands to her head to lift it. On the fifth day of the disease, there was marked improvement after saline aperient and four-grain doses of salicylate of soda, every four hours. In the morning the right upper eyelid was puffy, but the swelling went down again. There were slight droppings of blood from the nose three several times during the day. On the sixth day, after a restless night with some wandering, followed by a morning sleep of two and a half hours, the child woke up sufficiently well to listen to fairy tales and talk about them. She felt the neck so much better that she volunteered to get out of bed alone to show her throat, but still holding one hand lightly to the head. There was some sensitiveness to light, and the right eyelid was again puffed. The same evening great restlessness set in, the child throwing her legs and arms about and calling out. The tumefaction of the right eyebrow had now markedly increased, and there was strong delirium. Temperature 103.3°; pulse 140; respiration 38. Bromide of potassium was added to the salicylate mixture. After a sleep of an hour and twenty minutes the pulse was 120 and the temperature 101.6°. On the seventh day the right eyebrow was quite tense, glazed and livid, and delirium continued. At 10 a.m. the temperature was 104°. Two leeches were applied to the right temple, and three grains of calomel were given, to be followed by a saline purge. Towards evening the strength perceptibly diminished. Just after midnight the pulse was 138, respiration 52, temperature 105.7°. At 4.30 a.m. the temperature was 106.4°; at 6.30 a.m. the temperature was 107.7°; at 9.45 a.m. the temperature was 107.9°, and death took place at 10.45 on the morning of the eighth day from the commencement of the symptoms. The autopsy was made five hours after death. At once on removing the calvaria, the frontal portion of the longitudinal sinus showed itself overcharged, staining the periosteum externally. On lifting the brain, the dura mater covering the petrous portion of the right temporal bone was found smeared with thick yellow lymph. The same lymph smeared the pons and the parts comprised in the circle of Willis. The right temporo-sphenoidal lobe of the brain was protuberant, due to serous infiltration from obstruction to the venous return. The right optic nerve and the fat surrounding it were stained with the same clinging yellow lymph. The periosteum of the right orbital plate of the frontal bone was stained with inflammation, and destroyed in patches; the bone beneath was dead.—Mr. Pearce Gould asked if there was any pulsation noticed at any time in the orbital swelling, for thrombosis of the cavernous sinus had been alleged to be one cause of pulsating exophthalmos.—Mr. James Black asked if any fluctuation was made out, and whether an incision would

have been of any avail.—Dr. Mahomed asked if there were any blush or redness in the early history of the case. A case of necrosis of the frontal bone he had lately seen began as a red erysipelas-like swelling, and there were other signs of a septic nature of the affection, in the shape of multiple abscesses on the brain.—Dr. Broadbent said there was no pulsation and nothing like fluctuation in the swollen lid, which was quite soft and loose. The chief mischief was on the cerebral side of the bone; the dura mater was pierced in several places, while the periosteum of the orbit was intact, and the effusion within it was serous. He had considered that the free mobility of the eye and the entire absence of proptosis excluded any inflammatory effusion within the orbit.

Dr. George Johnson gave a demonstration on the Use of Picric Acid as a Test for Albumen and Sugar in the Urine. He said that although picric acid had for ten years or more been used as a test for albumen in the urine, its value had not been fully appreciated. It might be used in the form of a saturated aqueous solution, made by dissolving the crystals in about fifty times their volume of boiling water, or in the form of powder, which could conveniently be carried in a pocket-case. The solution poured on the surface of the urine in a sloping test-tube caused opalescence in a specimen of albuminous urine diluted much beyond the point at which nitric acid failed to act. The powder or crystals, equal in bulk to a peppercorn, when shaken up with about a drachm of urine would be dissolved, and immediately coagulate any albumen present. Picric acid boiled with a solution of potash was a most delicate test for glucose. The reduction of yellow picric to the deep-red picramic acid by glucose when boiled with potash, although noticed by Braun nearly twenty years ago, appears not to have been utilized as a practical test. One drachm of a solution of grape sugar, one grain to one ounce, was mixed with half a drachm of liquor potassæ (B.P.), ten minims of a saturated solution of picric acid, and made up to three drachms with distilled water. The mixture was placed in a boiling-tube ten inches long and three-quarters of an inch wide, having a mark made at the height of three drachms. It was then heated to the boiling point, and kept boiling for sixty seconds. The resulting color indicated a quarter of a grain of sugar to one ounce. This color might be exactly imitated by a solution of acetate of iron, with excess of acetic acid, which was used as a standard in making a quantitative analysis. The depth of color was directly proportioned to the amount of sugar present to decompose the picric acid. When the color was deeper than the standard, the dark liquid was diluted until it and the standard had the same tint. The dilution was effected in a tube twelve inches long, divided into equal 1-10 inch and 1-100 parts. By the side was a tube of equal size, containing the standard color. A more exact comparison of the colors was made by looking through equal columns of the saccharine liquid, and the standard in flat bottomed tubes held over white paper or porcelain. Ten minims of solution of picric acid is rather more than equivalent to the sugar (1.8 grain) in one drachm of a solution containing one grain to one ounce. In making an analysis the picric acid must be in proportion to the amount of sugar. If the proportion of sugar were as high as six grains to the ounce, about a drachm of solution of picric acid would be required for a drachm of the sugar solution. When the amount of sugar is more than six grains to the ounce, the liquid should be diluted in a definite proportion before it is analyzed. Distilled or pure rain water was used for dilution. If undiluted urine were rendered turbid by phos-

phates in process of testing, it should be cleared by filtration. The presence of albumen even in large amount does not interfere practically with the picric acid test. The accuracy of the test was proved by practically identical results from analyzing the same specimens by Dr. Pavy's ammonious cupric solution, and by the picric acid and potash. Some tabular statements of results were given. An analysis of about 300 specimens of normal urine by the picric acid process indicated the constant presence of a substance capable of reducing picric acid and cupric oxide in proportions equivalent to from 0.5 to 0.7 grains of glucose per ounce, but apparently differing from glucose in the fact that it cannot be made to undergo the vinous fermentation under the influence of heat, etc.—Dr. Andrew Clark thanked Dr. G. Johnson for his very interesting clinical communication. He thought that they had acquired a very important and quick method of analyzing with precision, both albuminous and saccharine urines.—Dr. Southey said that Dr. Johnson had exhausted the subject and had left little for others to say. He was very much indebted to him for his demonstration of the test. He had used picric acid since Dr. Johnson's first paper on it, and had found it very reliable and convenient. It had now been proved that normal urine contained minute quantities of albumen and sugar, and these very delicate tests were very important in enabling us to detect these small traces. It was daily coming out that normal urine of high specific gravity and of acid reaction contains albumen.—Dr. Mahomed asked for information on Dr. Ralfe's communication at the Pathological Society, in which he stated that it was also necessary always to test with heat to determine the kind of albumen present. They had heard that picric acid showed the presence of forms of albumen which were not thrown down by heat and nitric acid. He thought that more delicate tests for albumen were not wanted, but they did require a good simple working reaction which would quickly detect the presence of morbid quantities of albumen.—Mr. McHardy had found the picric acid test most valuable. He was sure it was important to recognize the presence of albumen in urine in which it could not be detected by boiling and adding nitric acid. He referred to a case of black eye which he examined ophthalmoscopically, and he then felt very sure there was albumen in the urine, as was shown by picric acid, but albumen could not be detected by heat and nitric acid. The man had tense arteries and distinct albuminuria retinitis. He had tried pouring strong nitric acid into a test tube, on to that suspected urine, and above that a concentrated solution of picric acid, and while a very slight reaction may be indicated at the lower edge of the stratum of urine, a very marked reaction will be obtained at the upper edge; kreatine masks the presence of saccharoid matter in the urine.—Dr. Johnson doubted very much whether there is even the smallest trace of albumen in urine as a physiological result. In reply to Dr. Mahomed, he contended that more rather than less delicate tests for albumen were needed. Dr. Mahomed had published several cases of Bright's disease (granular contracted kidney) in which he had failed to find albumen in the urine—many more cases than he himself had ever seen. Dr. Johnson thought that this discrepancy might have been avoided if Dr. Mahomed had used delicate instead of rough tests in examining the urines.

An inquiry is to be instituted into matters connected with the management of the Bedminster Fever Hospital.

PATHOLOGICAL SOCIETY OF LONDON.

Hypertrophy of Lower Jaw.—Rheumatoid Arthritis.—Fracture of Sternum.—Exostosis on Fibula.—Sacculated Bladder in Female.—Sarcoma of Bladder.—Sarcomatous Myo-fibroma of Uterus.—Charbon.—Tests for Albuminuria.

THE ordinary meeting of this Society was held on March 8th, Mr. J. W. Hulke, F.R.S., in the chair. Several specimens of considerable interest were shown, among which we may specially refer to the charbon pustules and bacilli from Guy's Hospital. Dr. Ralfe gave a very useful demonstration of practical points in connection with testing urine for albumen, and clearly showed that in the urine from a case of Bright's disease heat alone determined the presence of serum-albumen, the other tests only showing that some form of albumen was present in the other specimens.

Mr. C. Heath showed a woman of thirty-six years of age with Unilateral Hypertrophy of the Ramus of the Mandible. At twenty-five years of age she had an attack of left hemiplegia implicating the face; her limbs recovered, and so did her face, at least partially. During the last ten years the face had become deformed. The chin was pushed over to the right by hypertrophy of the left ramus of the jaw, the body being unaffected. The vertical length of the left ramus was three inches, the right one inch and a half. The motion of the jaw was restricted. The pathology was obscure. He referred to a somewhat similar case in Dr. Adams' work on Chronic Rheumatoid Arthritis, but in it there was distinct rheumatoid affection; there was nothing of this kind in his case. He regarded it as a case of hypertrophy which could be remedied by removing part of the jaw and producing a false joint.—Mr. Roger Williams said he had a specimen of hyperostosis of the angle of the jaw. The patient was a healthy young man. The angle of the jaw was removed; the bone was exceedingly dense.—Mr. Hulke said that in Mr. Heath's case there was no great enlargement of the articular end of the bone; in Mr. Adams' case there was.—Mr. Croft asked Mr. Heath what there was in this case to distinguish it from osteitis deformans, which it somewhat resembled. Had the woman had pains in the bones? This disease was very rare in so young a person. He thought the vascular supply was interfered with on account of the remarkable unilateral character of the affection.—Mr. C. Heath replied that the patient had had no pain. Sir J. Paget had declined to recognize it as a case of osteitis deformans. He would show a piece of the bone after removal.

Dr. Norman Moore brought forward Dorsal and Lumbar Vertebrae, showing rheumatic arthritis, from a Roman tomb discovered in digging the foundations of the library at St. Bartholomew's. The skeleton to which the bones belonged was entire, and lay in a stone sarcophagus preserved at St. Bartholomew's. The vertebrae showed lipping of the edges of the centra, irregularities on the intervertebral surfaces, and in some places anchylosis with considerable formation of osseous tissue. There was nowhere any loss of substance. In the middle dorsal vertebrae there was bony union on both sides, but lower down, though both sides of the centra were lipped, fresh bone had been formed on the right side only. Della Chiaje had described rheumatic arthritis in bones found at Pompeii, but the St. Bartholomew's tomb, ascribed by antiquarian authorities to the fifth century, had, perhaps, furnished the earliest case of the disease in England.—Mr. Bruce Clark men-

tioned a specimen, four or five centuries earlier, in the museum at Oxford—an atlas ossified to the skull. It came from a tumulus of before the Christian era, and was regarded by Professor Rolleston as the earliest specimen extant.—Mr. Croft said the term rheumatoid arthritis was loosely used, and he urged that it should only be employed in cases with a clear history of rheumatism.

Mr. Hulke said that many years ago an old Roman cemetery at Saffron Walden was dug up, and a large number of the bones presented the changes seen in these bones.—Dr. Norman Moore said it was very common to find deposits of urate of soda in joints without any history of gout; he therefore could not attach much importance to the absence of a history of rheumatism in cases of arthritis. He thought the changes in the bones were characteristic.

Mr. Arbuthnot Lane showed a specimen of Fracture of the Sternum at the junction of the first and second pieces, and Dislocation of the Second and Third Left Costal Cartilages from their Ribs. There was no fracture of ribs and vertebrae. He also described a form of articulation that was found in the first costal cartilage when it became sheathed in bone. This might be either a single arthrodial joint or one of two forms of mixed articulation. These conditions were exemplified in the specimen shown. Their purpose was to obviate the rigidity of the cartilage, and to allow of the free movement of the sternum in respiration.—Mr. Pitts thought it was difficult to account for the nodule of bone on the back of the sternum, which appeared to be a fragment of a comminuted fracture, and yet there was no indication of where the piece was detached from. Could the nodule be due to some secondary change about an old fracture? The point in reference to the joint of the first costal cartilage was a very interesting one.

Dr. Hale White showed a peculiar process on the Fibula in the Fibres of the Soleus, beginning one inch from the top of the fibula springing just above the oblique line on the inner side. He thought it was unique.—Mr. Morris asked if it was true bone or ossification of part of the tendon of the soleus. Such ossifications of tendons were not uncommon, especially in the tendons fixed to the great trochanter.—Mr. Hulke thought it similar to the processes developed in the adductor and deltoid muscles from constant riding and frequent bruising by the musket.—Dr. White said it lay in the muscular fibres; it was on one side only of the body; it was true bone.

Dr. Hale White also showed a Sacculated Bladder from a woman who had been under Dr. Wilk's care for hæmaturia and pyuria. She died, and on post-mortem all the viscera were healthy, except the bladder, where there was a small opening between the left ureter and the orifice of the urethra, which led into a cavity containing very offensive purulent fluid. This was a diverticulum from the bladder and larger than this viscus. There was a small abscess in one kidney and behind the uterus. The urine got shut up in the diverticulum, then decomposed, and it was impossible to cure the cystitis so caused. A sacculated bladder was extremely rare in the female, and one so large was very rare even in the male. In 3,000 autopsies twenty sacculated bladders were found all in men. In none of them was the sacculus large enough to attract notice during life. The only cause of sacculated bladder in the female was either spinal disease or pelvic cellulitis, setting up cystitis or causing abscess opening into the bladder.—Mr. Eve thought that such sacculatation formed as it were a safety valve, and that dilated ureter was infrequent

in such cases.—Mr. Barker asked if there was any evidence of obstruction in the urethra. Had the wall of the sacculus been examined? Dermoid cysts had been found to rupture into the bladder, and this might be such a case.—Mr. Croft asked whether if the bladder had been examined by the finger passed through the dilated urethra, the opening of the diverticulum could have been felt.—Mr. Morris asked if among Dr. White's cases there was any instance of sacculatation from enlarged prostate, which had caused the most marked example he had ever seen.—Dr. Norman Moore referred to the fact that Casaubon's bladder was sacculated; this was caused by enlarged prostate.—Mr. Hulke referred to a case recorded by Pott, who operated for a supposed hernia, and urine escaped, and it was believed that a bladder sacculus had got into the hernial sac.—Dr. White said no cause for the sacculatation was found in the urethra. To the naked eye there was no evidence of the sac being a dermoid cyst. Out of nearly three thousand autopsies at Guy's, there were twenty cases of sacculated bladder, eleven caused by stricture, five by stone, two by spinal disease, one by enlarged prostate, and one through epithelioma.

Mr. R. Williams showed two specimens of Sarcoma of the Bladder. In the first there was enlargement of the prostate, with a diverticulum of the bladder and a medullary sarcomatous growth in the diverticulum. The man had had difficulty in micturition for many years. A No. 10 English catheter passed easily. He complained of pain and weakness in the left leg. A tumour in the pelvis was detected, manipulation of which caused hæmaturia. At the autopsy the pelvic peritoneum was found pushed up almost to the umbilicus by a pelvic tumour. The bladder was flattened and compressed by the growth, and there was suppuration behind the bladder. The walls of the bladder were hypertrophied. About an inch above the orifice of the left ureter was the opening into a diverticulum larger than the bladder, and springing from the posterior wall of this diverticulum was the tumour above mentioned. The growth had pressed against one part of the bladder, and just at that spot was a small secondary growth from direct local implantation. The growths consisted of round cells, with tracts of spindle cells and myeloid cells, but no alveolar structure or cell nests. The second specimen was from the museum of the Middlesex Hospital. The viscus contained a growth fluffy on the surface. It was removed from a man aged sixty. No secondary deposits. Microscopically it consisted of branched villi covered with spheroidal epithelium; the deeper parts of the tumour were infiltrated with small round cells.—Mr. Bowlby doubted whether these cases were either of them sarcomatous. In the first the clinical history was too long, the suppuration was also very unusual, and microscopically the tumour consisted to a great extent of fibrous tissue. As to the second case, it was very rare to find sarcomata papillated, while under the microscope the fibrous tissue preponderated. He thought it was a soft fibroma; the cells found were simple connective-tissue cells.—Dr. Hadden stated that he recently made an autopsy on a man, aged sixty-three, who had suffered from pain and hæmaturia. He found a very large malignant growth springing from the trigone, white and fibrous. Behind the bladder were some enlarged glands.—Mr. Eve agreed with Mr. Bowlby that the tumours were not sarcomata. He thought that in the second case there were alveoli containing epithelial cells, and that it was a papilloma or carcinoma.—Mr. Williams replied that the two tumours were evidently quite unlike. In the second case there was fibrous tissue, no doubt, but the bulk of the tumour was

made up of small round cells. Villous sarcomata had been often described before. The first tumour was almost entirely composed of cells, and fibrous tissue was only seen where the tumour was lobulated. The local infective nature of the tumour was opposed to the theory that the tumour was a fibroma.

Dr. Finlay showed a specimen of Fibro-myoma of the Uterus becoming sarcomatous. The specimen was removed from a woman aged fifty-nine, who was admitted into the Middlesex Hospital under his care on October 4th, 1882. The patient had observed it for fifteen years, and it was only comparatively recently that it had given her any trouble. Eight days after admission she was seized with symptoms of peritonitis, and died on October 17th. Post mortem, the tumour was found to measure six inches by four and a half inches. It occupied the pelvic and lower umbilical regions, and was adherent to numerous coils of the intestines, one of which it had penetrated. It was attached to the fundus uteri by a pedicle about an inch in width. Its upper part was converted into an irregular ragged cavity, containing soft debris and blood-stained fluid; the lower part being firm in consistence, presenting the appearance of a uterine fibroid; it was whitish in color, and was surrounded by a distinct capsule. A smaller tumour about the size of a walnut, and presenting the ordinary appearance of a fibroid of the uterus, was attached to the lower part of the uterus. Secondary growths were formed at the base of the right lung, in the heart, and in the left kidney. Microscopically the tumour was found to consist in some places of round, and in others of spindle-celled growth separated by tracts of the normal structure of the fibro-myoma. There were also here and there patches of mucous degeneration; and in parts a considerable development of new bloodvessels, the walls of which were closely surrounded by the new cell formation. The secondary growths presented the same characters, except that in them the round-celled growth predominated over the spindle-cells. The generally accepted view that such tumours were degenerated fibro-myomata was adopted, and the fifteen years' history, the appearance of the growth itself, and the co-existence of the smaller benign growth pointed to as corroborating this opinion. Two cases figured by Schroeder in Ziemssen's *Encyclopædia* were referred to; and also two of a similar nature recorded by Mr. Hutchinson, and the late Mr. Callender, respectively, in the *Transactions of the Society* twenty-five years ago.—Mr. Eve said that in striped muscle fibre tumours of the kidney, round and spindle cells were found, which were transformed into muscle fibre. In Dr. Finlay's case might not the cells be developing into plain muscular fibre?—Dr. Dawson Williams said that in his case it was quite easy to see all stages between round cells and striped muscle; but it was not possible to assert that these round cells actually developed into muscle.—Dr. Finlay said that the fact of the metastatic deposits quite disposed of Mr. Eve's objection.

Mr. Davies Colley showed specimens from a Case of Charbon, which were obtained from a patient aged forty-three, who worked in leather. Five days before admission to Guy's Hospital he was struck in the face by a hide and scratched. He became restless and delirious that night; had a rigor, and severe itching in the scratch. On admission there was a bright-red swelling on the cheek, with abrupt edge, and a dark slough in the centre; the glands behind the angle of the jaw were enlarged. The man was very ill; temperature a little raised. The tumour was at once excised. The serum of the tumour contained abundant bac-

cilli (shown). The blood contained only micrococci. The patient has gone on well ever since. Next day he expectorated much mucus; his urine, faeces, and sweat contained bacilli (shown). They had had many cases lately at Guy's, as many as twenty-three in eleven years; already there had been four this year. In this case there was not a distinct ring of vesicles round the swelling as seen in the other cases, but the slightly depressed blackened centre was very characteristic. The constitutional symptoms came on very early, and although they had been present for four days, operation had apparently been successful. The bacilli were being excreted in very large numbers.

Mr. Bryant showed a specimen of Charbon Pustule taken from a man aged thirty-three, admitted a week after Mr. Davies Colley's case. He awoke three days before admission and noticed a small pustule on his face; the next day he was very ill, the swelling much increased, and the glands below the jaw were enlarged. He was admitted on the fifth day, almost cyanotic, very torpid, pulse 130, temperature over 100°; he had been retching. The characteristic sloughing condition of the skin was found in the face. The part was excised, but the man died collapsed in ten hours. Bacilli were found in the saliva and urine. Dr. Mahomed made the autopsy in Mr. Bryant's case. The stomach, intestine, and lung were diseased. The stomach and intestine were affected like the skin; a central slough with a halo of congestion surrounded it. Some of the sloughs were being detached; in the intestines the sloughs ran along the free margin of the valvula conniventes; in the cæcum the mucous membrane was immensely cedematous. In the lung little nodules occurred, about twenty in number; on section, they looked like hæmorrhagic infarcts; some were solid, others were hæmorrhages into the tissue. They, too, were probably of the same nature as the other lesions. The mesenteric glands, many of them, contained small hæmorrhages from infarcts of bacilli. There was an absence of the general oedema of the loose connective tissues which was commonly found. There were no subserous hæmorrhages nor pleuritic effusion. There were two pints of dirty bloody fluid in the peritoneum. At Bradford, where the poison was inhaled, nearly all the cases showed pulmonary symptoms and changes. The intestinal lesions were completely absent. At Strasburg the intestinal lesion was constant, probably from eating diseased animals. At Guy's the anthrax nodules were seen on the skin. The variations in the disease had led to varied classifications. The case showed recovery from intestinal anthrax; the sloughs were being separated satisfactorily. The patients died from cyanosis, the bacilli deriving oxygen directly from the red corpuscles. This might give an indication for treatment, to oxygenate the blood.

Dr. C. Ralfe showed four specimens of Albuminous Urine, each of which contained a distinct variety of albumen. He brought forward the subject with no view of deciding the merits of the rival tests, as suggested by Dr. G. Johnson, Dr. Pavy, and Dr. Oliver, but to draw attention to the fact that heat, and heat alone, would decide whether the albumen was serum-albumen or not, the really important clinical question after all. Dr. Ralfe pointed out that the cumbersome spirit-lamp might be done away with altogether if only a one-inch square of copper gauze were carried in the pocket; this held above the gas or candle-flame would prevent the test-tube becoming blackened. After the meeting Dr. Ralfe briefly demonstrated his facts. He spoke highly of Dr. Oliver's test-papers, which, if heat were employed in all cases as well, would give reliable results.

MEDICAL SOCIETY OF LONDON.

Elephantiasis of the Lower Limb.—Recto-Vesical Fistula; Colotomy.—Femoral Hernia, with Rupture of all its Coverings.

THE ordinary meeting of this Society was held on February 19th, Mr. Francis Mason, President, in the chair.

Dr. Heath Strange exhibited a girl seventeen years of age, the subject of Enormous Dilatation of the Lymphatics of the Left Lower Extremity, leading to great enlargement of the thigh, calf, and foot (elephantiasis), and a discharge of milky fluid from rupture of vessels in the thigh. She had been under observation since infancy. Vaccination at three months of age was followed by a general eruption on the face, hands, and buttocks, leaving scars, especially on the left side. At seven years of age the calf commenced to swell, the swelling, which was painless, gradually extending to the thigh and foot. At the age of nine she was an inmate of Great Ormond-street Hospital, under Dr. Cheadle's care for three months, the swelling having diminished, but her general health was greatly debilitated. The swelling returned, with attacks of pain, heat, and redness of the surface of the leg, and severe constitutional disturbance. The skin became darker, tubercular patches formed on the dorsum of the foot, at the roots of the toes, on the inner ankle, and on the margin of the inner side of the sole of the foot, after exercise. A small punctiform opening appeared on the inner side of the thigh, and commenced to discharge a white, milky fluid, having a faint, disagreeable odor. The fluid was often ejected with considerable force, and later there was discharge also from the tubercles on the foot. Crusts formed on the foot, and the leg again swelled; then, after an attack of severe inflammation and great pain in the knee, "something appeared to give way," the pain ceased, and the limb has gradually decreased, although there has been no discharge for the past five months. The calf, which measured eighteen inches and a half in circumference, and the foot, fourteen inches and a half, are now reduced to nearly the same size as the right, but the shaft of the tibia appears enlarged, and the left foot is still slightly larger than the right. Treatment was rest, bandaging, generous diet, and alterative tonics, cod-liver oil, and the syrup of the iodide of iron.—The President asked as to the duration of the discharge, and alluded to a similar case under his care.—Sir Joseph Fayrer pointed out the distinction between local affections and elephantiasis. There was similar hypertrophy of the tissues, etc., but true elephantiasis is the local expression of a constitutional disease, and is limited to certain tropical regions and their seaboard, not extending far inland. He doubted the origin of the disease from filariæ of the blood, as they were sometimes absent, and he had never known local treatment of any avail except in some young people, who could be moved from place to place. Elephantiasis occurred very seldom in persons of unmixed European blood. In some nations removal to a drier climate appeared to have been of service. He had tried ligature of the femoral artery without success; the swelling was reduced as long as the patient remained in bed after the operation, but recurred on his resuming work. Similar temporary reduction followed bandaging. In elephantiasis of the scrotum excision of the tumour often removed the constitutional disease.—Mr. Edmund Owen thought the term "elephantiasis," as applied to these cases of simple hypertrophy, to be of no pathological value, merely suggesting a superficial

resemblance. Although hypertrophy due to disease of the lymphatics was more common in the tropics, still cases are occasionally met with here, and he was inclined to attribute them to chronic inflammatory changes.—Dr. Routh inquired if the source of the lymph used in vaccinating the patient was known. He thought it possible to produce an artificial elephantiasis, and had seen such a case where nitrite of amyl had been accidentally introduced into a morphia injection.—Mr. Bryant thought the possibility of curing the disease by removing the local manifestation not inconsistent with received views of a filarial origin. He knew of a case in Leicester where the disease had apparently been transmitted through three generations, and none of the members of the family had ever left the town. Although unable to explain the good effects of ligation of the femoral, complete cure had followed this procedure in a case of his, and in another case temporary cure had followed ligature of the superficial femoral alone. He had seen elephantiasis in a man who had never left England, and in two boys, sons of a West Indian, but brought up in England.—The President exhibited three photographs of Elephantiasis Scroti. Sir J. Fayrer did not consider the cases met with in England as examples of true tropical elephantiasis, which begin with febrile disturbance and rapid hyperplasia, followed by slower growth. On removal of the growth the constitutional disturbances cease.—Dr. Crocker said that the condition of elephantiasis might be produced in various ways. He had had much success with the elastic bandage.—Dr. Heath Strange, in reply, said that the discharge continued constantly for several months, and then ceased altogether. The fluid was not examined. The veins were not apparently enlarged. The aspect of the limb was that of phlegmasia dolens.

Mr. Ballance related a case of Fæcal Abscess communicating with the rectum, ileum, cæcum, and bladder. A navy lieutenant, twenty-seven years of age, was the subject of chronic dysentery following an acute attack three years previous to coming under notice. Eighteen months later flatulency began to pass per urethram, and continued to do so for three months before any fæcal matter was observed to escape by this channel. When first seen he was greatly emaciated, and was suffering from a spurious diarrhoea. Much feculent matter and gas passed by the urethra; the urine was very offensive. There was fulness above the pubes, extending more to the left than the right; constant and severe pain was experienced at the neck of the bladder and the posterior part of the urethra, which morphia at least failed to relieve. The small intestine was thought not to be involved, because of (1) the length of time the patient had lived since the onset of symptoms; (2) the character of the fæcal matter; and (3) the history of dysentery. Right colotomy was performed. Death occurred suddenly on the tenth day. The post-mortem examination revealed a tight stricture of the rectum, above which three apertures led into a fæcal abscess situated above the bladder. The abscess also opened freely into the bladder, and by smaller apertures into the ileum and cæcum. Mr. Ballance remarked that the colotomy would probably have been more successful if it had been performed earlier, when only the rectum was involved, and raised the question whether in such a case as the above external urethrotomy would have been the better course. Such a measure would have given rest to the bladder and urethra. He also suggested in such cases of vesico-rectal fistula the performance of a colotomy—stretching the proximal end of the divided colon to the abdominal wound; but after uniting the cut margins of the distal end

returning this portion of bowel into the abdominal cavity.—Mr. Black thought colotomy the best mode of giving relief in this class of case.—Mr. Bryant thought the cause of the fistula in this case more common than was usually believed, and more common than in cancerous ulceration. He had performed colotomy in two such cases with permanent relief, and argued against the postponement of that measure. He thought the perineal drainage hardly feasible.

Mr. Bernard Pitts read notes of a case of large Femoral Hernia, where sudden rupture of its coverings occurred, and a portion of intestine was protruding for several hours after reduction. A woman, aged forty-six, who had a large femoral hernia of twenty years' standing, and who had been operated on at Guy's Hospital for strangulation of the same two years previously, had lately left off wearing her truss. On the evening of December 4th, whilst walking upstairs, she sneezed violently, and immediately felt something give way in her right groin. She found on examination that a portion of intestine had escaped through a rent in the skin covering the hernia. She was sent to St. Thomas's Hospital, and operated on directly after arrival there. A portion of the small intestine with mesentery about one foot and a half in length protruded through a rent in the skin one inch long, situated a little above the old operation cicatrix. The intestine was very bruised, dirty, and cold. It was well cleansed with carbolic lotion. The opening in the skin was enlarged freely, the crural ring slightly enlarged, and the protruded intestine, together with several feet of intestine found in the sac, were returned into the abdominal cavity. The sac and the redundant skin were afterwards removed, and the neck of the sac secured with stout catgut. The patient made a good recovery. Mr. Pitts remarked on the singularity of the accident and the reasons that led him to attempt a radical cure.—Mr. Edmund Owen observed that the case was probably unique. Femoral herniæ which had once been operated on were apt subsequently to assume large proportions. A few years since he had operated on a lady for strangulated hernia, who, twenty years before, had passed through the same kind of trouble. After this first operation there had been free sloughing of all the integuments. The patient did well after the second operation. In neither of these operations, nor in the present case, had the spray been employed.

Excision of Hip in Early Stages of Disease.—Dupuytren's Contraction in a Female.—Ascites in a Child.

At the meeting of the Medical Society of London on Feb. 26th, Mr. Francis Mason, President in the chair, Mr. Pye read notes of a case of Early Excision of the Hip-joint, and rapid recovery with a very movable false-joint. The child, between three and four years old, was admitted into the Victoria Hospital for Children four weeks after the onset of symptoms of hip-disease; but there was so much suppuration and exhaustion that operation was not delayed. A large abscess in the upper part of the thigh was laid open, and on exploring the cavity the head of the femur was found to be all but detached, and it broke off in the fingers. The excision was performed in the usual manner, the bone being divided below the great trochanter. The acetabulum was healthy. A Bryant's double splint was applied, and the prone position maintained for three weeks. Convalescence was rapid. There is one inch shortening; but movements of rotation, flexion, and adduction are perfect; abduction is limited. Attention was drawn to the com-

pleteness of the recovery; the early age of the patient and the growth of the limb since the operation, the extreme rapidity of the destructive process and the advantage of the prone position in after treatment.—The President said he was rather in favor of waiting in such cases.—Mr. Edmund Owen said that had not the result in this case been so satisfactory he would have suggested that the excision might have been limited to the intracapsular portion of the femoral diaphysis.—Mr. W. Adams thought excision should be undertaken as soon as the presence of diseased bone was made clear.—Mr. Pye in reply, said Listerian precaution was not followed in this case.

Mr. Fisher exhibited a female patient, fifty-two years of age, with well-marked Dupuytren's Contraction of both Hands. It commenced two years ago in the left hand, with drawing down of the little finger. The first phalanx is drawn to nearly a right angle with the metacarpal bone, and the second phalanx is flexed in the first, almost touching the palm; on the right hand the ring and little fingers are involved. The condition is rare in females. The present subject does much hard manual work; has never had gout, but her father suffered from it. Mr. Fisher contrasted this with a condition of flexion of the little finger, independent of contraction of the palmar fascia, the first pharyngeal joint alone being implicated, a condition common in young females. In answer to the President, he stated that no operation had as yet been performed, but he intended to undertake it on both hands in succession.—Mr. W. Adams had only seen three cases of Dupuytren's contraction in women, two depending on gout. Contraction of the fascia and its digital prolongation was essential for certainty of diagnosis.—Mr. Black stated that an example of this contraction in a female was at present in the dissecting-room at Westminster Hospital.—Dr. Hare protested against attributing this and similar affections to gout without full evidence from family or personal history, and the result of examination of the blood or serum. He had seldom seen this affection in cases of gout.—Dr. Roedel said the affection was common in Germany, where gout was very uncommon.—Dr. Ewart thought the affection frequently associated with gout; at any rate, contraction of the fingers was often found in persons who inherited or manifested gout. Were not the various forms of contraction but stages of one disease?—Mr. Adams, who replied for Mr. Fisher, admitted that the pathology of these cases was very obscure. He had never operated on those cases which could be treated successfully by prolonged mechanical means. Other forms might depend on contraction of the tendon, but in Dupuytren's contraction the fascia was implicated, and he believed it to be gouty in origin because of its being found more often in the upper classes of society, and in butlers and footmen rather than in the working classes, because of its being symmetrical, often inherited, and often associated with gout.

Dr. Day exhibited a girl eight years of age, who, on May 6th, 1882, was admitted into the Samaritan Hospital under his care, with symptoms of abdominal dropsy. For three months before admission her abdomen had been increasing in size. Copaiba, iron, digitalis, and purgatives failing to diminish the dropsy, paracentesis was performed on June 16th, and fifty ounces of fluid withdrawn. This was followed later by elaterium, and she subsequently became quite well under iron and digitalis. Dr. Day thought that anemia and some cachectic states of the system arising from deficient food and insanitary conditions might alone produce ascites. When the fluid resisted absorption and the general health was failing, he recommended

paracentesis, followed by tonics, good living, and active aperients.—Mr. E. Owen suggested that the case was one analogous to hydrocele.—Dr. Routh had met with cases of ascites dependent on faecal accumulation.—Dr. R. Lee alluded to the transitory enlargement of the abdominal glands in children apart from tuberculosis, and depending on slight intestinal derangement. In scrofulous children such enlargement becomes permanent. In other cases, the temporary obstruction to the portal circulation from pressure by these glands passed away under rest and proper diet. In Dr. Day's case, however, active interference was necessary.—Dr. Ewart said the glandular condition would not account for the effusion, though it might explain the slowness of absorption. The greater number of cases of ascites are due to portal obstruction; in children from a condition of subacute cirrhosis, frequently associated with rickets; often from tuberculosis of the liver. Mercurial treatment and purgatives were of most avail in such cases.—Dr. Day, in reply, did not think the ascites in his own case was due to glandular or portal affection, but to debility or some constitutional condition; and, in fact, was analogous to hydrocele. Cases which recovered under mercurials and purgatives were usually of this class.

The annual general meeting of this Society was held on March 5th, when the election of officers and Council for the ensuing year took place, and the reports of the Librarian, Treasurer and of the Council were read and adopted. The report of the Council entered into full detail concerning the important building operations which the Society had initiated during the past year, and which were now well advanced. The number of new Fellows admitted showed an increase over former years, and the Society has every reason to be satisfied with its position. By next session it will be in possession of premises which will not only afford it ample library accommodation, but a meeting room of considerably larger size than the present. Silver medals were awarded to Mr. Edmund Owen, the retiring Secretary, and to Dr. Whipham for his valuable paper on Bacilli in relation to Tuberculosis. The Fothergillian Gold Medal has been awarded to Mr. Norman Porritt, of Huddersfield, for the best essay on the Operative Treatment of Intrathoracic Effusion; five essays were received in competition for this prize. Votes of thanks were cordially passed to Mr. Francis Mason, the retiring President, to the retiring members of Council, and to Mr. Edmund Owen, the retiring Surgical Secretary; and the votes were acknowledged in suitable terms by Mr. Mason and Mr. Owen, who alluded to the fact that, in spite of the inconvenience attending the building operations, the Society had continued its weekly meetings without interruption. At the close of the business of the general meeting, Dr. Broadbent read notes of two cases illustrative of the value of the cold douche in delirium tremens and in pyrexia, and a discussion followed, in which Sir Joseph Fayrer, Dr. Althaus, Dr. Gilbert Smith, and others took part. The following gentlemen were duly elected to the several offices:—President: Sir Joseph Fayrer. Vice-Presidents: Dr. J. Hughlings Jackson, Mr. John Cawood Wordsworth, Dr. John Bruntton, Mr. Alfred Cooper. Treasurer: Dr. Alfred Wiltshire. Librarian: Dr. William Henry Allohin. Honorary Secretaries: Dr. Isambard Owen, Mr. Alfred Pearce Gould. Secretary for Foreign Correspondence: Sir William MacCormac. Council: Mr. Henry Francis Baker, Mr. Samuel Benton, Dr. Sidney Coupland, Mr. John Hamilton Craigie, Dr. Henry Radcliffe Crocker, Mr. John Henry Drew, Dr. Wm. Ewart, Dr. James Kingston

Fowler, Dr. Heneage Gibbes, Mr. David Henry Goodsall, Mr. George Lawson, Mr. Henry Morris, Mr. Francis Mason, Mr. Edmund Owen, Dr. Sansom, Dr. Charles Brodie Sewill, Dr. Gilbert-Smith, Dr. William Heath Strange, Mr. W. J. Walsham, Dr. Theodore Williams.

On Thursday, March 8th, the Fellows of the Society dined together at the Criterion Restaurant.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

THE ordinary meeting of this Society was held on March 8th. Mr. Mason, of Bath, presided in the absence of Mr. Bowman, and announced that the meeting in June will be devoted to a discussion on the relation of eye diseases to affections of the spinal cord. Dr. Gowers is to be invited to open the discussion.

Mr. James E. Adams showed drawings of the Fundus Oculi from a milliner, aged sixty-one (exhibiting the ophthalmoscopic appearances at periods long subsequent to embolism of the central artery), who suddenly lost the sight of the right eye on July 5th, 1871, and of the left in a precisely similar manner on Aug. 24th, 1881. The arteries in each eye contained scarcely any blood, and many of them were quite thread-like; the veins here and there showed old inflammatory changes, and one large trunk in the left eye was "beaded." There were also well-marked traces of old neuro-retinitis, and the maculae were occupied by well-defined patches of chroido-retinitis.—Mr. Nettleship asked if the patches near the yellow spot were due to secondary chroiditis or to retinal swelling, which seemed to him to be more likely.

Mr. Adams thought that the changes were at first purely retinal. He believed such changes would be found more frequently if they were looked for.

Dr. C. E. Fitzgerald, of Dublin, read a paper on the Connection between Disease of the Eye and Affections of the Sexual Organs in Females. The author, after alluding to Dr. Mooren's paper on Disturbances of Vision and Uterine Diseases, said that though the existence of a connection between diseases of the eye and affections of the genital organs in females would probably be admitted by most medical men, yet the literature on the subject was extremely scanty. Professor Förster (article in the handbook of Graefe and Saemisch) had placed the matter on a surer basis, but nevertheless it was unsatisfactory. He then related a case in which a violent neuro-retinitis occurred some time after a sudden cessation of the menses. The vision improved under treatment and with the reappearance of the menses. In a case of disseminated chroiditis with floating opacities in the vitreous, multiple fibroid tumours of the uterus were found; and it was suggested that possibly these tumours affected the circulation, so as to react injuriously on the delicate vascular tissue of the eye. Dr. Mooren had drawn attention to the subject of masturbation in proof that an irritation of the vagina might have an influence in producing retinal hyperaesthesia or accommodative asthenopia. Dr. Fitzgerald believed that the habit was practiced by females much more frequently than was generally supposed, and mentioned three cases in which he believed it had acted most injuriously upon the eyes. He considered the subject one of grave importance; and that, however unpleasant it might be, it ought to be thoroughly investigated.—Mr. Hutchinson could add little of a definite character to what Dr. Fitzgerald had stated on this very important matter. He had

given a lecture on this subject, in which he stated that there were organic diseases of the eye produced by masturbation in both sexes. But such cases had been very few in his own experience. Muscæ were common as a result of masturbation. He had no evidence of choroiditis disseminata from reflex disturbance from genital disease. He had seen several cases of softening of the vitreous from masturbation. He saw much of the ill effects of the habit in both sexes, cases in which the nervous system suffered greatly and in which the eye remained intact. He could not contribute any facts in connection with uterine fibroids or chronic metritis as exciting diseases of the eye. He referred to a severe case of muscæ in a lad of fifteen, caused by repeated sexual intercourse.—Mr. Spencer Watson thought that there were some cases illustrating the connection of sexual disorders and ophthalmic diseases. At the menopause, congestion of the head often occurred, and if the choroid were diseased, hæmorrhages were liable to occur. He had brought forward a case in point.—Mr. Benson thought that masturbation was not a disease of the sexual organs; it was often a symptom rather than a disease, and a central nervous lesion might be the cause of both the ill habit and the eye affection. He suggested that the eyes of monkeys should be examined with a view of throwing light upon this subject.—Dr. Buzzard had seen cases of disturbance of the general nervous system from masturbation, but nothing more serious than difficulties in accommodation in the visual organs.—Mr. Fitzgerald said that in many cases masturbation was not due to central affection; asthenopia was very frequently associated with leucorrhœa, which he thought was often produced by masturbation.

Mr. W. Adams Frost exhibited a living specimen of Pulsating Exophthalmos, affecting both Orbits. The patient was a man, aged thirty-eight, who, when ten years old, was run over, and had symptoms of fracture of the middle fossa of the skull. Since the accident a pulsating swelling had existed above the left eye, and he had heard a drumming noise in the head. Until within the few last years the left eye was very prominent. When exhibited, however, the eye had ceased to be prominent, and he suffered no inconvenience. The eye was rotated inwards, and beneath the eyebrow was an oval swelling the size of a filbert; in the angle between the nose and the orbit there was a flatter and more diffuse swelling. There was pulsation in both swellings, and a thrill in the nasal portion. Above the right eye was a small soft pulsating swelling. A loud bruit was audible over the left orbit. Pressure on the left carotid arrested pulsation in both orbits. Mr. Frost was of opinion that the symptoms were due to a fracture of the base crossing the left internal carotid artery, and establishing a communication between it and the sinus, which had led to varicose distension of the orbital veins, and that this varicose condition had extended by the circular and transverse sinuses to the veins of the opposite orbit. He reviewed the evidence afforded by the necropsies of nineteen cases which were on record, and pointed out that, in the majority of these, an arterio-venous communication was present, and that in nearly all the cases the pulsating swelling was formed by the distended orbital veins. The frequency with which symptoms of fracture of the skull were present in similar cases was also referred to.—Mr. Higgins suggested that an arterio-venous communication within the orbit might in some cases account for the symptoms.—Mr. Pearce Gould stated that a case of pulsating tumour of the orbit was in Middlesex Hospital under Mr. Hulke's care at the present time; the common carotid artery was liga-

tured, and it was hoped that a cure had followed, when a slight thrill and pulsation recurred at the inner corner of the orbit. He also referred to a specimen in the museum of the hospital taken from a man in whom during life there were all the signs of pulsating exophthalmos, but nothing abnormal could be found after death.

Dr. D. Little related a case of Sarcomatous Tumour of Iris, with successful removal. The subject was a young and healthy woman, aged twenty, and was first seen by him on June 20th, 1880. Sixteen months previously her left eye became suddenly blind while in the act of stooping, and remained so for a week. On recovering sight she for the first time observed a spot on the colored part of the same eye. Her family history was good. The tumour was situated on the lower and outer quadrant of the iris, extending from the papillary margin to the periphery of the iris; it was the size of a small pea, of a pale-brownish color, with a few fine vessels on its surface and numerous red points. The eye in every other respect was healthy, and free from irritation, and the vision was normal. On November 20th, 1880, the tumour had slightly increased in size, and it was decided to remove it. The patient was put under ether, and a linear incision was made with a Graefe's knife close to the corneo-scleral junction; the tumour and the corresponding piece of the iris were removed without difficulty; there was no bleeding into the anterior chamber. In the course of three weeks the eye had fully recovered, and the vision was equal to 20-20. It was then more than two years since the operation was performed; and up to three months ago there was no evidence of recurrence, and the vision was normal. The specimen was handed to Dr. Dreschfeld, Professor of Pathology, Owens College, for microscopic examination. The mass consisted almost entirely of round cells, containing a large round nucleus, filling up nearly the whole of the cell, and showing in its centre one or more highly refractive nucleoli. There were also a few spindle-shaped cells with nuclei; only a few cells contained brown pigment; the blood-vessels were all of the embryonic type. The microscopic examination thus showed the tumour to be a pigmented, round-celled sarcoma. A similar case had been recorded by Dr. Kipp in the *American Journal of Ophthalmology* for 1876, and three others by Dr. Knapp in the same journal for 1879.

Mr. Arthur Benson (Dublin) read a paper on Paralysis of some of the Ocular Muscles after Diphtheria, and gave some particulars of a case which had recently been under his care. The patient was a girl, aged eleven years. The primary throat affection was cured in four weeks. The ciliary muscles were affected in the fifth week, and continued so for about seven weeks. The soft palate was affected in the sixth week, and remained so for about two weeks. The hearing was affected in the sixth week, and remained so for about one week. The levatores palpebrarum were affected in the ninth week, and continued so for about one week. The recti externi muscles were affected in the ninth week, two days after the levatores palpebrarum, and remained so for about three weeks. The strabismus and diplopia convergens were present during the tenth week, and lasted for about four days. The weakness of the lower extremities began in the tenth week, and lasted for about three weeks. Numbness and tingling in the feet began about the tenth week, and lasted for about the same time as the weakness, three weeks. He regarded paralysis of the ciliary muscle, without alteration of the condition of the iris, as the most frequent implication of the intrinsic muscles of the eye. The seat of the lesion was, he be-

lieved, in the brain and spinal cord, and he combated Dr. Hughlings Jackson's sympathetic theory on the grounds that disease of the lenticular ganglion would be accompanied by some change in the action of the pupil. The portion of the nervous system, lesion in which would cause isolated bilateral paralysis of accommodation, was, he thought, Hensen's and Voelcker's centre for accommodation in the hinder part of the floor of the third ventricle. The deafness, on which Dr. Jackson laid stress as confirmatory of his theory of disease of the optic ganglion, was, Mr. Benson thought, more likely to be the result of the palate paresis, with which it was accompanied, than of interference with the nervous supply to the tensor tympani muscle. Paresis of both levatores palpebrarum and of both external recti muscles, as well as the frequent occurrence of paralysis in distant parts of the body, and perverted sensation, all disproved the sympathetic hypothesis. Dr. Ferrier had found that, at the base of the first frontal, and extending partly into the second frontal convolution, there was, in the monkey, an area of irritation of which caused elevation of the eyelids. Disease of this centre would account for the ptosis, which was bilateral. As to the nature of the lesion, but little was known. Post-mortem examinations had shown in many cases numerous hæmorrhages into the nervous centres, and in some cases a swollen condition of the large motor cells in the anterior cornua of the cord. Such changes, though they might occur in fatal cases, seemed unlikely to be the cause of paralysis, so fugitive and harmless as diphtheritic paralysis usually was. Mr. Benson thought that hæmorrhages, larger or smaller, numerous or few, as the case might be, were a more probable cause. Hæmorrhages had in several cases been found in diphtheritic paralysis. Hæmorrhages might be of any size, and the symptoms would be severe in proportion to the extent and position of the extravasation. Small hæmorrhages might be absorbed with great rapidity, and have but little, if any, ill result; larger hæmorrhages would account for the hemiplegic and other grave forms sometimes seen.

The following card specimens were shown by Mr. Arthur Benson: 1. A retino-ciliary Artery—i.e., a branch from the central artery of the retina, which apparently went to join the ciliary arteries by doubling back, and penetrating the disc near its border. 2. A Recent Spontaneous Detachment of the Retina, showing a rent in its structure. 3. Retinitis from Cerebral Disease, simulating retinitis albuminurica. 4. Retinitis Albuminurica (typical). 5. A peculiar condition of the Vitreous, with Disease in the Macula and Metamorphopsia. 6. Opaque Nerve-Fibres (typical case), with some disease about the macula.

Dr. Samuel West exhibited a woman with Dislocation of Lens of twelve years' standing, who, twelve years earlier, had "knocked her eye against the corner of a table;" vision at once became gravely affected. The right pupil was dilated to the extremest degree, and presented a notch on the upper part, corresponding with a linear scar in the sclerotic and cornea. The lens lay free in the vitreous, and moved with the eye; the retina, optic disc, and choroid were atrophied.

EPIDEMIOLOGICAL SOCIETY.

A MEETING of this Society was held on Feb. 7th, 1883, Dr. George Buchanan, F.R.S., President, in the chair.

Deputy-Surgeon-General A. C. C. De Renzy, C.B., read a paper on the Sanitary State of the British Troops in Northern India, of which the

following is an abstract. The object of the paper was to estimate the results of the measures taken to improve the health of the British troops in India since the date of the issue of the report of the Royal Commission on the Indian Army. The author first proceeded to fix a standard of comparison. He rejected the oft-quoted death-rate given by the Royal Commission—viz., 69 per 1,000—as a standard, because it was founded on the results obtained in a period of incessant war—viz., from 1800 to 1856—and was to be regarded rather as a statement of the cost in life at which the British Empire in India had been built up, rather than as an estimate of the rate of mortality existing at the time when the report was issued. He took the death rate of 1862, the year in which the Royal Commission submitted its report, as closely approximating the average death-rate of the troops at that time. The death-rate of that year, which was by no means a healthy one, cholera in a virulent form having visited many stations, was 27·25 per 1,000. The author then referred to a table showing the death-rate for each year from 1862 to 1880. This period was one of almost unbroken peace, except in the years 1879 and 1880, and, in order to make the statistics of those years fairly comparable with those of the previous years of the series, the figures relating to the troops on field service in Afghanistan were excluded from the table. The most marked feature in the table was the extraordinary fluctuations in the death-rate, which ranged from 11·64 to 42·89 per 1,000. The death-rate of the later years was shown to be quite as high as that of the earlier ones of the period. The death-rate of 1880 was 27·73, that of 1862 being 27·25, per 1,000. The death-rates of individual stations, as shown in another table, confirmed the conclusions indicated by the statistics of the Presidency as a whole. The stations continue as before to be subject to the most destructive epidemics, one or two years healthy, and then visited by cholera or enteric fever in a most virulent form. In 1877, for example, Morar had a death-rate of 12, and in 1878 one of 65, per 1,000. Peshawur had a death-rate of 3 in 1877, and one of 141 in 1879. Another point clearly shown by the statistics of stations was the fact, of constant occurrence, that in the same season, of two stations at a very moderate distance apart, one was extremely healthy, while the other was decimated with cholera or enteric fever, proving conclusively that the epidemics were not due, as was usually supposed, to some general atmospheric influence. After showing that nearly half of the total mortality was due to cholera, dysentery, diarrhoea, enteric, and other fevers, the author discussed the causes of the excessive mortality from diseases so eminently preventable. He sketched the general sanitary conditions of Indian cantonments, but entered into a very full description of the state of the water-supply, which he considered the key to the whole matter, and he gave in detail an account of the numerous opportunities which occur in that country for the pollution of drinking water. The Royal Commission summed up their conclusions on the water-supply as it existed twenty years ago in these words: "It will be seen that the supply for permanent stations is the same as that usually adopted for armies in the field, somewhat similar methods have always been in use in uncivilized, or imperfectly civilized, populations." Great improvements have been made in other matters; magnificent barracks have been built at a cost of ten millions sterling; 26 per cent. of the troops have been located in the hills, but the water continues, in the author's opinion, in a state unworthy of a civilized people, and this is the reason why the death-rate has not fallen, and why epidemics

of cholera and enteric fever continue so common. After quoting several high authorities, whose opinions on this point differ widely from those of the author, the case of Fort William, in Calcutta, was referred to as one in which sanitary requirements, as they are understood in England, were fairly satisfied. It is surely an encouraging fact that, while in the decade ending in 1880 the average death-rate of the troops stationed in the United Kingdom was 8.68 per 1,000, the death-rate of the troops stationed in Fort William in the same period was only 10.60 per 1,000. The prevalence of intemperance was referred to as an indirect effect of the present system of water-supply, cool, drinkable water not being procurable, the men acquire a craving for alcoholic drinks. The paper concluded as follows:—"The subject thus imperfectly dealt with is one of immense importance. The fabric of the British Empire in India visibly rests on the health of the British troops; but the importance of the subject extends far beyond them, it concerns the teeming millions of the native population. Orientals are fatalists; epidemics, they believe, are special dispensations of Providence with which it is idle, if not injurious, to interfere. When, as a sanitary commissioner, I endeavored to convince native municipalities of the error, I was met by the argument, that if epidemics were preventable, why did not Government prevent cholera among the British troops? The constant recurrence of destructive epidemics among the British troops is the greatest obstacle to the progress of sanitary improvement. To refute Oriental fatalism, a clear demonstration of the preventability of epidemics is required; and such a demonstration can be best made in military cantonments." The author then submitted that the facts and figures laid before the meeting warranted the following conclusions:—1. That since the publication of the report of the Royal Commission in 1862 there has been no appreciable reduction in the rate of mortality among the British troops in Northern India. 2. That, with very few exceptions, the water-supply remains substantially in the state described by the Royal Commission. 3. That so long as the water-supply remains in this state the health of the troops will be at the mercy of any accident which may convey to them the contagia of such diseases as cholera and enteric fever. 4. That the case of Fort William affords ground for hope that the measures which have so reduced the rate of mortality in that fortress would produce equally good, if not better, results in the naturally more healthy stations of the North-West Provinces and Punjab.—In the discussion which followed, the President, Sir Joseph Fayrer, Drs. Dickson, Gordon, Soriven, Manifold, Murray, McConnell, and Mr. Shirley Murphy took part.

MIDLAND MEDICAL SOCIETY.

At the ordinary meeting held in the Birmingham Medical Institute on Feb. 21st (Dr. Malins, President, in the chair), Mr. Eales showed a young girl, aged fourteen, who had been affected with a sudden and rapidly increasing Exophthalmos accompanied with Optic Neuritis. After a few days' duration the exophthalmos began to subside, a discharge of fetid pus taking place from the right nostril at the same time. There was no conclusive evidence of hereditary syphilis or struma, but frontal headache had been experienced for three months before. Mr. Eales considered this to be a case of caries of the bones between the cavities of the orbit and the nose,

with formation of pus and perforation into the orbit, thus setting up orbital cellulitis.

Mr. West exhibited a boy whose left knee-joint had been widely opened, the result of an accident. Suppuration followed, but under strict antiseptic measures there was a perfect recovery in six weeks.

Mr. Chavasse showed two large Sarcomatous Tumours recently removed. The first originated at the upper third of the shaft of the tibia in a girl, seventeen years of age, and was as large as a foetal head. The history extended over a period of six months, and before admission to the General Hospital the tumour had been incised as an ordinary strumous swelling. The limb was removed at the upper third of the thigh and a rapid recovery ensued. The second case was that of a girl, aged twelve, who had complained of pain in the right shoulder joint for two months, which was attributed to rheumatism. One month before admission to the hospital a tumour was noticed over the right scapula; this rapidly increased until it was the size of a man's clenched fist, and was accompanied by emaciation. The whole of the scapula was removed, but the patient died of shock seven hours after the operation. Both tumours were mixed forms of sarcomata, and of periosteal origin.

Dr. Windle exhibited the following specimens: 1. A large deposit of carcinoma in a left kidney, secondary to scirrhus mamma of two and a half years' duration; the patient was a female aged sixty-two. This is the only secondary deposit. After removal of the breast very little urine was passed, and none at all the day preceding death. The fatal termination occurred six days after the operation. 2. Renal calculi. Right kidney very small, containing several calculi, and the gland structure was very much destroyed. The left kidney was larger than normal, but otherwise unaltered. 3. Right kidney containing one large branched calculus and one small round one. The substance of the gland was much destroyed. The left kidney was a mass of structureless fat containing a small calculus.

Mr. Priestley Smith read a paper on the Use of Eserine in Glaucoma, in which the action of the drug in the usual forms of the disease was discussed. It was shown that the opposite effects of eserine and atropine on glaucomatous tension are not due to any influence over secretion, but to changes in the mechanical relations of the iris. Whenever atropine or eserine produces any pronounced changes in the tension of the eye, they do it by altering the relations of the iris in such a way as to injure or promote the escape of the intra-ocular fluid. This assertion was supported by comparing clinical experience with the facts discoverable by dissection in the chief varieties of glaucoma. A series of drawings from specimens of glaucoma were exhibited. In forming an opinion as to the propriety of using eserine in any individual case, the question should be asked, Is there any obstruction in the eye which is capable of reduction by contraction of the pupil? The author advocated caution in the use of the remedy; inasmuch as where it does no good it is apt to do harm, because it increases the flow of blood through the vessels of the iris, and indeed it has been known to induce hæmorrhage. Also it should never be allowed to stand unduly in the way of operative treatment, for the cases in which eserine by itself suffices to cure are few in number.

Mr. West read a paper on Chronic Joint Inflammations and their Treatment, which he illustrated by various cases that had been under his care. He reviewed the pathology of such inflammations as they occurred in the synovial membranes, ligaments, and bones, and the effects which were subsequently produced on the cartilages. He advo-

cated immobilization of the limb, or rest by the weight extension, together with the application of ice and freezing mixtures to the surface of acutely inflamed joints; where considerable effusion exists aspiration and free antiseptic incision should be employed. Mr. West considered that Listerism had revolutionized the treatment of joint inflammations, and there should be no hesitation in laying open any inflamed articulation.

HARVEIAN SOCIETY OF LONDON.

At the meeting on March 1st, 1883, the President, E. Symes Thompson, M.D., in the chair, Mr. Edmund Owen made some remarks upon the simple treatment of Congenital Talipes. He said the commonest form was that in which the heel was drawn up and the foot inverted, talipes equino-varus. He had found the best treatment for this form was division of only the tendo Achillis, then the application of a tin splint for three days, after which gentle manipulation should be practiced, the heel being brought down and the foot everted. Then a plaster-of-Paris bandage should be applied to the limb in its corrected position, and kept on for three weeks, and then reapplied if necessary. Mr. Owen showed a patient with double talipes equino-varus, on whom he was practicing this method of treatment, and put on a plaster-of-Paris bandage.

Dr. Percy Boulton then read a paper on the Treatment of Post-partum Hemorrhage. He pointed out first the differentiation between this and other forms of puerperal hemorrhage, and after speaking of ordinary cases and their treatment, he discussed the treatment of extraordinary cases or those of the major degree, and passed in review the value of cold, heat, injections of iron, and transfusion. He particularly urged the more frequent use of transfusion, believing that 50 per cent. of those who now die from puerperal hemorrhage would be saved if no woman were allowed to die without transfusion having been previously tried. He was in favor of direct or immediate transfusion from vein to vein with the simple apparatus used by Professor Schäfer in his experiments on animals, which was cheap, took up no room in the obstetrical bag, and did not get out of order. In the absence of a human blood-giver, he thought a salt-and-water solution, at a temperature of 110° F. and of a strength of one drachm to the pint, should be always used, the quantity of the injection being determined by the result. He gave the following objections to mediate transfusion, in which the blood is drawn first into a vessel and defibrinated: 1. Loss of time during bloodletting. 2. Cooling of blood during whipping, which necessitated artificial heating and further loss of time. 3. Chances of embolism from imperfect defibrination. 4. The necessity of a more or less complicated pumping apparatus, very apt to get out of order and to have fibrin deposited on its valves, and so cause embolism. 5. Contamination of blood with bacteria, either during defibrination or from the instrument rarely used getting fouled inside. He thought the use of a cheap, portable, simple instrument such as he exhibited to the meeting, which could not get out of order, and could always be at hand, and the adoption of a saline solution when a blood-giver was not forthcoming, were the most likely means of popularizing this operation.—A discussion ensued.

—We regret to notice the death of Dr. Palfrey, the senior Obstetric Physician to the London Hospital.

Editorial.

KOCH ON THE BACILLUS OF TUBERCLE.

DR. R. KOCH seems determined to plunge into controversy. Hardly has he delivered himself of an attack upon M. Pasteur's methods and conclusions upon the subject of anthrax vaccination than he feels called upon to reply to the various objections that have been raised to the import of his discovery of the bacillus tuberculosis. In the issue of the *Deutsche Medizinische Wochenschrift* for March 10th he pens a lengthy reply to each writer who has ventured to deny the specificity of the bacillus, and this without discriminating between criticism that was based on actual research and that which is almost purely theoretical. Nor is the manner of his reply to be commended, for it certainly will not conciliate. Indeed, at Vienna it has already raised a spirit of opposition, which can bode no good for the attainment of the truth. He finds opponents to his doctrine mostly in America and Germany. In the former country there is Cutler, who regards the bacilli as the embryonal forms of the mycoderma aceti; Rollin Gregg, who suggests that they are really only fibrin filaments; Schmidt, of Chicago, who believes they are fat-crystals. Such statements are so easily disproved that one wonders that Koch takes the trouble to refer to them. More powerful opposition comes from Formad, who has not only declared his inability to detect the bacilli in some cases of caseous destruction of the lung, but avers that other forms of bacteria give the same result to staining reagents. He also reviews the fact of the proclivity of certain animals to tuberculosis after non-specific inoculations, being, as Koch remarks, apparently ignorant of the work done by Cohnheim and Salmonson on this point. Koch advises Formad to make himself acquainted with the recent literature of artificial tuberculosis, and to distinguish between spontaneous and inoculated tubercle. Strassburg's failure to find bacilli put him out of court in the denial of their existence. Turning to German opponents, he first meets Beneke, who doubts the significance of bacilli from the fact that alcoholic and ethereal extracts of blood yield products having the reaction of the bacillus; and upon this Koch merely recalls the fact that in 1876 a well-known botanist declared the anthrax bacillus to be merely a form of crystal. Cramer has found in healthy stools bacilli giving the color reactions of the tubercular bacillus, but other observers, as Menche and Gaffky, have also examined these excretions in non-phthisical persons with negative results. Even granting the resemblance between such bacteria and the bacillus tuberculosis, it has yet to be shown that they possess the same pathogenic characters. Koch says he has never denied the possibility of other bacteria having like color-reactions to the bacillus of

tubercle, but he has never met with such, the bacillus lepræ excepted. He likewise throws doubts on Baloch's alleged discovery of similar bacilli in the slime from the Berlin drains. Schottelius is another adversary who has lately written in support of tuberculation by non-specific substances, disregarding the extension of tuberculosis and its infectivity, and considering that the bacilli have no etiological relation to the disease. The same writer also contends against the identity of human with bovine tuberculosis, and advances facts against the communicability of the latter to man. Dettweiber discriminates between phthisis and general tuberculosis, and, although he has found the bacilli largely in cases of phthisis, does not admit their causal relation. Koch, however, gathers from his remarks that he has incompletely grasped the teachings of bacterial pathology. The last and most important observer who has thrown doubts upon the discovery of Koch is Dr. Spina, assistant to Professor Stricker, of Vienna, who has recently issued a *brochure* in which he goes over the whole ground covered by Koch, the first attempt, according to the latter, in this direction. His conclusions were wholly at variance with those of Koch, who deals very severely with him. Koch points out that the method followed by Spina is very defective, that he has not followed the precautions which every worker in the subject of micro-organisms must adopt if he wishes to avoid error; that consequently his "cultivations" are untrustworthy and his inoculation experiments (limited to but two rabbits) inconclusive. Koch does not think such work, in spite of the high praise accorded to it in Vienna, should for one moment be reckoned on a level with his own experiments, conducted upon hundreds of animals, with every precaution. He goes further, and avers that Spina shows himself to be ignorant of the methods of examination, cultivation, and inoculation of bacteria. He believes that the result of his labor will be to discredit not only the observer himself, but the institute to which he belongs, and satirically recommends him to study bacterial pathology *de novo*. From this it will be gathered that Dr. Koch has written very warmly in defence of his facts—perhaps too warmly—and has, moreover, not been free from a certain tone of contempt which hardly befits his position, and is less likely to advance his cause than if he had discussed the matter more temperately and judicially.

At the time of writing we learn that Professor Stricker has entered the list in defence of Dr. Spina, who has worked in his laboratory for thirteen years, and is at present virtual director of the microscopical department. Stricker desires to share the responsibility of Spina's publication, with the main points of which he was acquainted. He further declares that Koch's experiments prove nothing as to the contagiousness of tuberculosis, and refers to his own work on the subject, and the abundant testimony from observers in all parts of

the world, as to the production of artificial tuberculosis by inoculations of indifferent materials. He also points out that the fact that putrefactive bacteria stain with Koch's reagents (a fact discovered by Spina and vouched for by Stricker himself), destroys the main argument advanced by Koch in favor of the specific characters of the tubercle bacillus. Professor Stricker's remarks were made at the annual meeting of the leading medical society at Vienna; and he concluded by saying that Spina is preparing a further statement, which will clearly expose the position taken by those who speak so magisterially without previously testing by experiment the work they criticise. There is thus open war between Vienna and Berlin about the tubercle bacillus.

VIVISECTION.

THE current number of the *Contemporary Review* contains an article on the Anti-Vivisectionist Agitation, by Dr. E. De Cyon, and a reply by Mr. R. H. Hutton. We must confess to being at a loss to understand the exact object aimed at by thus again introducing this subject in such a place, and having read the articles, we fail to see that either of them advances the discussion in any particular. It is but fair to remember that Dr. De Cyon is writing chiefly, if not entirely, in fulfilment of a pledge, that he is writing not in his native tongue, and with confessedly an imperfect knowledge of the details of the "agitation" in this country. Dr. De Cyon is quite as much annoyed with the conduct of the profession in this country in this matter as he is with that of his opponents. He considers that the profession has made a grave error in carrying on "a scientific discussion with the persons whom interest or eccentricity has led to declare against the laboratories," with "outsiders whose judgment has no value at all in matters of science." Such a line of conduct he regards as excessive condescension, and as certain to be unsuccessful, and he would have preferred to see agitation met by agitation, petition by counter-petition, and every weapon turned against the enemies of science which had been so skilfully and unscrupulously used against themselves. We do not agree with Dr. De Cyon, but we thank him for his statement, as it has been the cause of eliciting from Mr. Hutton a sweeping condemnation of the policy and action of his many "anti-vivisection" allies. These are Mr. Hutton's words: "No reasonable person ever fancied for a moment that any one but a physiologist is competent to criticise the physiological ends which the physiologists propose to themselves in vivisection." We are glad to have such high authority for considering many of the opponents of vivisection mere unreasonable agitators. Dr. De Cyon gives several examples of the wholly dishonest use made by the "anti-vivisectionists" of this country of diagrams and garbled sentences from his "*Physiologische Methodik*." In this there is nothing new, but the facts stated

are so disgraceful, that we are astonished that any body of men and women professing to be moved by more than ordinarily high and pure motives should resort to such contemptible and dishonest means of prejudicing their opponents and of furthering the adoption of their views among the unthinking and the ignorant. Mr. Hutton is silent in regard to this, and writes as if this meanness were consistent with a "sheer sense of justice and humanity" by which alone he is influenced in this matter. After defending himself from the charge of cruelty, Dr. De Cyon criticises with some severity his assailants, and shows that of the two leaders of the movement against vivisection in Germany, one was ignorant of the matter, and the other, well-informed, was actually insane at the time he wrote against physiological experiments. Mr. Hutton's article deals exclusively with Dr. De Cyon's, and he has somewhat closely followed the latter in all those features which he indicates as errors. Attaching blame for imputing motives to the leaders of the "anti-vivisection" agitation, he does the same himself not only by assuring his readers that his associates "have joined in the movement from a sheer sense of justice and humanity, and for no other motive whatever," but by repeating the odious charge against Dr. Klein that his correction of his first evidence before the Royal Commission was untrue, and that his later statements did not represent the true state of his mind. Mr. Hutton's argument is summed up in one sentence: "What we do maintain, however, is this—that there is a much higher moral object in prohibiting torture, *even for the discovery of new truth*, than any which you can plead for experiments involving torture; and of the relative importance of cherishing humane habits and promoting scientific discovery the general public are just as good judges as" Dr. De Cyon. What Mr. Hutton may mean by "torture" we cannot pretend to know, for it is used in the most various senses; but if we take it as denoting severe and prolonged suffering, it is at once evident that Mr. Hutton's "moral object" is not obtained by prohibiting the larger number of physiological and pathological experiments. His words surely mean, in reference to any vivisection, "no pain, no immorality." He is scarcely, therefore, in a position to support the existing law, much less to advocate a more stringent measure for the complete suppression of all vivisection. But of course we cannot accept Mr. Hutton's view even in this sense, for we believe that the "moral object" in pursuing investigations for the discovery of truth which shall be of advantage to all succeeding generations of men or animals, or both, and the means of prolonging or saving life and mitigating suffering, is far greater than any which can arise from the protection of a few individuals from pain, in most cases very slight, and in but rare instances severe. Such a view is in harmony, we believe, with the truest philosophy and the workings of nature, and is a

principle of almost universal application. But after being told by Mr. Hutton that no "reasonable" layman is competent to criticise the physiological ends which physiologists propose to themselves in vivisection, it is surprising to find him stating that the general public are as able as the profession to judge of the importance of promoting scientific discovery. Can Mr. Hutton give one single instance in which the public have shown as correct an appreciation of the value of scientific discovery as the laborers in science themselves? And to be ignorant of the value of a discovery carries with it ignorance of the value of promoting such a discovery. Nor is the other part of the comparison Mr. Hutton would draw more valid. We very much doubt whether the general public know much about the value of humane habits. Certainly inhumanity stalks through this and every other land, and the true meaning of humanity is understood by few and practiced probably by fewer still.

OBSERVATIONS ON LEPROSY.

THE problem as to what is to be done towards lessening the prevalence of leprosy and mitigating the sufferings of lepers in our dependencies, appears from papers before us to have advanced a step in the Bombay Presidency. From returns furnished by the Commissioners of the several Divisions, at the instance of the Bombay Government, it appears that there are, excluding Bombay city and the district of Ratnágiri, where there is a leper hospital founded by private munificence, 9,483 lepers ("black" or true leprosy). The disease prevails only to a slight extent in Sind and Kánara, to a greater extent in Gujerát and the Southern Marátha country, and is common in the Deccan and the coast districts of Thána and Kolába, reaching a maximum in Khándesh, where there are 2,186 lepers, forming 177 per cent. of its population. This return, which was instigated by the application of the joint secretaries of the Sassoon Infirm Asylum at Poona for a Government leper asylum to relieve their institution and allow it to more fully carry out the object for which it was originally founded, seems to have powerfully impressed the Government with a desire to mitigate the evil, and to act on the able and repeated suggestions of Dr. Vandyke Carter, that the only practical method of dealing with the matter is by the *segregation of lepers*. In short, the Governor fully recognizes the desirability of establishing leper asylums in the Presidency, and as sufficient Government funds are not available, he earnestly seeks to enlist the help of private philanthropists. Meanwhile valuable observations are being made in the contagion and heredity of leprosy in countries where the conditions are more favorable than such a region as India. Popular belief has pointed all the world over and in all times to the propagation of leprosy by contagion, but the writings of Daniellssen and Boeck, and the reports of Virchow

and the English College of Physicians, seemed to show that leprosy was hereditary, but not contagious by mere contact, although it was left an open question as to inoculation through abraded skin. Since the date of these reports many have come forward to dispute the conclusions, especially with regard to contagion. Heredity has not been so much assailed, and we have in syphilis an instance that a disease may be both contagious and hereditary. Hansen, in Norway, it is well known, has adduced strong arguments in favor of the contagiousness of the disease, but he attacked the view of its hereditariness. The inquiry, in regions where leprosy is endemic, is almost hopelessly confused by the fact that it is impossible to exclude the possible factors of contagion and the common exposure to the influence of some morbid agent. It is objected to the heredity view that the numerous statistics show a wide divergence of results as to its degree, and that the evidence of direct heredity is not strong. It is also a matter of common experience that only one or two of the children of a leper may be attacked, and these not in any regular order in the family. Then, again, in all probability children are never born with the evidences of leprosy upon them. Mr. Hillis says that although very favorably placed for the observation, he has never seen it; yet this may be explained by the very chronic evolution of leprosy. Hansen noted that in a district where leprosy is of recent origin, the indications of heredity are slight or absent, and that it is not until the disease has become endemic that the supposed proof is forthcoming. Lastly, Morehead, as well as Lewis and Cunningham at Almora, came to the conclusion that heredity could not be a great factor in the increase of leprosy in a district, inasmuch as lepers have comparatively small families, who suffer a high rate of mortality, and, therefore, the survivors are only just numerous enough to replace their defunct progenitors.

Dr. I. E. Atkinson published in the *Archives of Medicine* for June, 1882, the details of the case of undoubted tuberculated leprosy in a married woman, forty years of age, of German parentage, who had never left the State of Maryland. Her children and husband were healthy, and the only traceable origin was to a tuberculated leper whom she had known for two years, and who lived next door for one year. Dr. James C. White, of Harvard University, also recently contributed to the *American Journal of the Medical Sciences* an ably-written paper on the question of Contagion in Leprosy, in which he concludes that heredity is not the all-important factor in its propagation, though he would not exclude the possibility of its operation in individual cases, but that leprosy is communicable from man to man by direct transference, like syphilis, probably by inoculation of some of the juices and products of disintegration of the leprosy foci.

DIABETIC COMA.

THE subject of sudden death and fatal coma in diabetes is one so intimately bound up with the nature of the disease itself that it is surprising that attention should have been paid to it only in recent years; for of all modes of termination this is perhaps the most frequent, and the explanations put forward for its occurrence have none of them been found of general application. In a valuable paper contributed to the last volume of Guy's Hospital Reports, Dr. Fredk. Taylor reviews the subject in the light of the experience of that hospital, and deals with twenty-nine cases of diabetic coma out of a total of forty-three fatal ones. Fourteen of these twenty-nine cases were uncomplicated; and of the remainder, three were combined with old phthisis, seven with recent phthisis or pneumonia, one with ulceration of the bowels, two with pyelitis and suppurating kidneys, and one with carbuncle and granular kidneys.

The same subject is dealt with by Professor Frerichs, of Berlin, in the current number of the *Zeitschrift für Klinische Medizin*, and its appearance is a timely one for physicians in London, who are now engaged in discussing the morbid anatomy and pathology of diabetes at the Pathological Society. The writer speaks from a large experience of the disease, no fewer than four hundred cases having passed under his hands; but he refrains from any statistical conclusions as to the frequency of death by coma and collapse, as many patients passed away from notice, or died at a distance from causes of which he has no accurate record. He is, however, possessed of a sufficiently large record to show that a rapidly fatal termination is more frequent in this disease than is generally accepted, and to justify the remark that the diabetic lives in constant jeopardy. The fatal result may occur through syncope from cardiac paralysis, from collapse, with more or less general functional nervous disturbance, insensibility, delirium, somnolence, and coma, often, but not always, accompanied with a sense of anxiety and by severe dyspnoea. Sometimes no exciting cause can be discovered for this event. In other cases, excessive physical exertion, mental emotion, or anxiety determine it; and more often still it is preceded by some local disease, such as gastric catarrh, constipation, tonsillitis, alveolar abscess, etc., or the more formidable onset of bronchitis and pneumonia. Whether they be only of the nature of epi-phenomena or not, the urgent symptoms (which occasionally pass away for a time) may be arranged into three distinct groups, each of which Professor Frerichs illustrates by examples. In the first group he places those cases where the diabetic, generally after some exertion, is attacked suddenly with general weakness, cold extremities, feeble pulse, somnolence, and loss of consciousness, death ensuing in a few hours. In the second group the symptoms are more pro-

longed, and are usually preceded by symptoms or such local affections as are above mentioned. Then occur headache, restlessness, delirium, great anxiety, sometimes a maniacal state, dyspnoea with or without cyanosis, a weak and rapid pulse, low temperature, somnolence, and coma. The breath in these cases has often the odor of chloroform or acetone very marked. Exceptionally the drowsiness passes away, to recur later, or to be followed by more lasting improvement. The whole cycle of events may be run through in twenty-four hours, but the condition generally lasts from three to five days, sometimes longer. In the third group of cases there is no dyspnoea, and the strength seems fully maintained, when the patient is attacked with headache, giddiness, and drowsiness passing into coma; the breath here also has the characteristic odor, and the urine yields the burgundy-red tint when tested with perchloride of iron. Any or all of these events may be associated with the inflammatory local affections met with in diabetes—as erysipelas, pneumonia, meningitis, etc. Professor Frerichs makes a few remarks upon the diagnosis, prognosis, and treatment of the condition, and shows how futile have been all attempts to save life on the several plans proposed; and he passes on to discuss its cause and nature. These have been sought (1) in changes in the nerve centres, and the most various lesions have been described—as hyperæmia, œdema, hæmorrhage, etc.; but none of these are constant, and are all probably explicable as results rather than causes of the initial disturbance. Nor is there any solid evidence in support of the view that the symptoms are due (2) to an inspissation or other alteration of the blood; microscopical and spectroscopical examinations show no evidence of such change. Again, the symptoms have been attributed (3) to uræmia, and there is a certain similarity in the symptoms due to this cause and to diabetic coma. Moreover, in some cases the urine is much diminished or suppressed, or albumen may appear in it; but this is by no means invariable, and the symptoms are not the same as those of uræmia, which does carry off a certain number of diabetics who have organic renal disease. Of late years much attention has been directed to another process—(4) fat embolism—to the occurrence of which the cases related by Dr. Sanders and Professor Hamilton afforded such strong support. Frerichs remarks that fat embolism has not been observed in the brain, although met with in many other organs; and he has never detected it himself, although he has carefully sought for it. In only one case was the blood at all milky, and in that case no emboli were found. Moreover, examination of the blood during life does not reveal an excess of fat. Then comes the question (5) of acetonæmia, which, since the discovery of acetone in the urine in diabetic coma by Pelters, in 1857, has been regarded as the cause of this condition. Much remains to be ascertained concerning the occurrence of acetone

and the products that precede its appearance; but this much is known, that acetone injected into the blood of animals does not produce symptoms of coma; and Frerichs thinks that the term "acetonæmia" should be discarded. The characteristic reaction with perchloride of iron is due to the presence of acetic ether, but the same reaction is given by aceto-acetic acid, and neither of these substances produces the characteristic symptoms of diabetic coma in animals. Lastly, the symptoms have been referred (6) to defective elimination, based on the fact that more or less extensive necrotic changes occur in the renal and other epithelia in diabetes, as well as a hyaline degeneration of the tubes of Henle in the kidney. But, as is shown in an appendix to this paper, these renal changes are due to the deposition of glycogen in the affected tissues; and they occur in all cases of diabetes, whether death be ushered in by coma or not.

The conclusion at which Professor Frerichs arrives is not, then, very satisfactory, but it shows how much yet requires investigation. There are probably various causes in operation, and the first group of cases differs markedly from the others. In it death takes place from cardiac failure; there are no nervous symptoms, and the characteristic odor of the breath and reaction of the urine are absent. It is due to cardiac degeneration, owing to rapid tissue-waste, and other unknown factors which may operate in preventing tissue regeneration. The symptoms of the second and third groups are those of intoxication. A series of changes take place in the blood, the final products of which—aceto-acetic acid and acetone—are known, but the initial products of such fermentation in the blood itself are unknown and difficult to ascertain, from the rapidity with which the process takes place. The value of the paper is enhanced, by two elaborate appendices, one by Dr. Ehrlich, demonstrating by means of iodine the invariable presence of glycogen in the renal cells at the junction of the medulla and cortex of the kidney in diabetes, the presence of the same substance in other tissues and in inflammatory exudations being as constant as in the non-diabetic organism; and the other by Dr. Brieger upon chemical researches with respect to diabetic coma, particularly as to acetone and its allies.

THE MORAL OF THE MONASTERIO "CASE."

THERE is nothing that calls for special remark in the Monasterio case. It is simply an instance of misadventure, possibly of intentional wrongdoing, though upon that issue we cannot offer any opinion, in the working of a system which, except to those who are officially committed to its approval or support, seems to be specially devised with a view to facilitate the occurrence of grave misadventures and the doing of great wrongs. The Lunacy laws of France may be worse in their

minor details, or they may be either more carelessly or less conscientiously administered than our own, but the same radical defect is common to both. Any medical man, with or without a special knowledge of mental diseases, is empowered to sign a certificate of lunacy, which is, in fact, a *lettre de cachet*, or warrant for the arrest and imprisonment of the person named therein. Nor is the committal made to a prison—or asylum—provided by the State, and under official management. The place of confinement is, in fact, a private establishment, on a footing, in that respect, with the old sponging-houses to which debtors were once hurried. The proprietors of private asylums for the insane very strongly object to the licensed houses under their control being described as “prisons,” or in any way compared thereto. We do not employ the term, or suggest the comparison, in a spirit of carping or hostile criticism, but it should once for all be understood, and continually borne in mind by our readers of all classes, that we are wholly opposed to the private asylum system as at present existing, and that we earnestly desire to see it reformed, not, indeed, by the abolishment of private asylums for the insane, but by placing those institutions on a satisfactory footing as regards the interests which proprietors or lessees have in the reception and retention of patients. We contend that the State should take over the private asylums as it has taken over the telegraphs, or at least empower municipalities and country boards to acquire and manage such property. The moral of the Monasterio case does not, however, so much relate to the private-asylum system as to that of “certifying.” Here lies the great fault of the mode of procedure both in France and in England. No non-official person, whether medical or clerical or legal, ought to have the power of making what is practically a secret order for the removal of an alleged lunatic to an asylum. Certificates should in no case be given by private individuals engaged in practice for fee. It is a mistake to suppose that the endorsement of certificates thus given by a magistrate would afford the smallest security. In a case of lunacy, which is so self-evident that a magistrate can himself recognize the existence of mind disease, his endorsement of the certificate must be unnecessary. If, on the other hand, the insanity is not, so to say, *overt*, no layman—we will go further and say no one but a man who has specially studied mental disease—can possibly form a judgment of any real value. In short, the magistrate is no more use in the matter of lunacy than he would be in a doubtful case of fever or obscure disease of any description, simply because he cannot make a special medical diagnosis. As to the supposed safeguard afforded by the mere countersigning of a certificate that may be dismissed as worthless. Unless the person countersigning can form a judgment of the actual needs of the case, he must be guided by his opinion of the practitioner, and

neither the public nor the profession would consent to the exercise of magisterial functions on such a basis. Until certificates are given by official medical men not engaged in private practice, and properly qualified for the task of examining the insane, cases like that which has just attracted attention in France must occasionally occur. We have said that we cannot form any opinion as to the *bona fides* of the medical men concerned in the case of Mlle. Monasterio. There is simply nothing to guide us. We have too often, unhappily, in England, to condemn hasty examinations. All we can say is that precisely what has happened in this *cause célèbre* may happen again under similar circumstances, and without the smallest intentional wrong-doing on the part of the medical men concerned. It is the system that is bad—rotten to the core, but not yet rotten enough, it would seem, to secure a legislative remedy.

Reviews and Notices of Books.

The International Encyclopædia of Surgery. Edited by JOHN ASHHURST, Jun., M.D. In Six Volumes. Vol. II. pp. 754. London: Macmillan & Co.

THE second volume of this work has succeeded the first within a comparatively short interval, and Dr. Ashhurst has by his selection of contributors again given to the profession, both in America and in this country, a series of very valuable contributions to medical literature. The present volume contains the following articles: Contusions, by Dr. Hunter McGuire; Wounds, by Thomas Bryant; the Antiseptic Method of Treating Wounds, by W. Watson Cheyne; Poisoned Wounds, by John Packard; Sabre, Bayonet, and Arrow Wounds, by Dr. J. H. Bill; Gunshot Wounds, by Dr. P. S. Connor; Effects of Heat, by Dr. Thomas Morton; Effects of Cold, by Dr. J. A. Grant; Abscesses, by Mr. Howard Marsh; Ulcers, by Dr. J. T. Hodgen; Gangrene and Gangrenous Diseases, by Dr. E. M. Moore. Venereal Diseases: Gonorrhœa, by Dr. J. W. White; Chancroid, by Dr. F. R. Sturgis; Syphilis, by Dr. Arthur Van Harlingen; Bubon d'Emblée, etc., by Dr. H. R. Wharton. Surgical Diseases of the Skin and its Appendages, by Dr. J. C. White; Diseases of the Cellular Tissue, by Dr. Joseph W. Howe; and lastly, Injuries and Diseases of the Bursæ, by Charles B. Nancrede. It will thus be seen that, with the exception of the articles of three Englishmen, Mr. Bryant, Mr. Cheyne, and Mr. Howard Marsh, the whole of this volume is written by American physicians. A good reflex is consequently obtained of the views and modes of treatment employed by our brethren across the Atlantic in some subjects, especially in that of gunshot wounds, in which their experience has been exceptionally extensive. Dr. Ashhurst states in the preface that the late Dr. Otis, the justly distinguished author of the “Surgical History of the War,” responded with enthusiasm to his request that he should undertake the article on Gunshot Wounds, but failing health interfering with his ability to work, he put off the task from time to time, and died before he had written it. The editor, however, has, in our opinion, every reason to be satisfied with Professor Connor, of Cincinnati, who has supplied Dr. Otis's place, and, who has evidently had very large experience, has

written a really excellent article on gunshot wounds.

Dr. J. H. Bill's article on Sabre and Bayonet Wounds, and on Arrow Wounds, is extremely interesting, the latter part of the article being to English readers original. Sabre wounds, he says, are very rare in modern warfare owing to reduction in the cavalry arm and to the changes in the duties now performed by it. As usually employed, the sabre has a dull edge, and the wounds it makes are more or less contused, but they heal as readily as incised wounds, though they are more apt to be followed by scars. The number of wounds inflicted by the bayonet appears from the statistics collected by Dr. Bill to be very small. Of 11,900 British wounded in the Crimea, there were only seventy-six cases of bayonet wound, with seven deaths, and eighty-seven of sword wound, with one death. In the American war of the Rebellion, out of a total of 400,000 wounds there were 22,700 incised and 5,900 punctured wounds, but few of these were inflicted with sabre or bayonet. The fact is that the bayonet can only be used at close quarters, and one party or the other gives way and retires—not to say runs—before the weapons are actually crossed. It is also true, however, that as Dr. Bill states, the soldier dislikes to use his bayonet. He was told by an officer engaged in the Mexican War, in 1846, that at the capture of the City of Mexico he saw soldiers firing their muskets into the bodies of certain of the enemy to whom quarter had been refused, with the bayonets actually resting against the persons of the slain. In regard to arrow wounds, which are still seen in the fights the Americans have with Indians, the bow-and-arrow is so formidable an instrument, that Dr. Bill thinks it not impossible that it may again become a military weapon, especially in the hands of cavalry. The arrow, by reason of its velocity, has great penetrating power, and when it has once entered it is grasped by the tissues with amazing firmness, so that it is extremely difficult to extract, even when the shaft is still present. When the head alone remains imbedded, it is almost impossible to accomplish its removal, which, however, is absolutely necessary without enlarging the wound. He depicts some ingenious instruments that have at various times been employed for the purpose of extracting the head. The arrow can be aimed at fifty yards as correctly as the revolver, and can be shot nearly as fast. Indeed Dr. Bill thinks that at close quarters and in a *mêlée*, it is a weapon more to be trusted than the pistol. Is it possible that in the revolution of time we shall have butts in Hyde-park and a body-guard of archers, who would of course be Scottish, for Her Majesty? The cause of death from arrows are usually hæmorrhage and peritonitis.

The subject of Gonorrhœa, by Dr. J. W. White, is treated very fully in the following order: History, nature, varieties; which in the male include the typical or acute form, the subacute form, and irritative or abortive gonorrhœa, with their complications—gleet, strictures of large calibre, seminal plethora, urethral anesthesia, and neuralgia from urethral irritation; in the female the subject is discussed under the heads of treatment, varieties, and complications; and lastly, Dr. White discusses gonorrhœa in anomalous situations. The drug named Kavakava, from Fiji, is mentioned, and is reported to have a marked action upon the genito-urinary tracts. Chronic gleet is said by Mr. Kesteven to yield readily to its effects, and in chronic cystitis it possesses an influence superior to any other remedy with which he is acquainted. Dupuy considers it to be a sialagogue, a bitter tonic, a gentle excitant of the nervous system, a powerful diuretic, and a blennostatic. Balsam of

gurjun, or wood oil, is stated to have been used with advantage as an anti-blennorrhagic. In the treatment of chordee Dr. White recommends the employment of bromide of potassium, which he thinks has fallen into undeserved neglect. He also mentions an excellent plan originally suggested by Dr. Scarenzio—of the hypodermic injection into the perineum of from one-fourth to one-fifth of a grain of morphia in solution when the chordee is persistent and very painful. Dr. White recommends the employment of opium suppositories and of a sufficient number of leeches to take away from eight to ten ounces of blood. He has little faith in soluble bougies, such as those containing iodoform, tannin, acetate of lead, carbolic acid, and oil of eucalyptus. In treating of vulvitis and vulvo-vaginal abscess as a complication of urethra, a good table is given, setting forth the points of diagnosis between this disease and pudendal hernia, cyst of the labium, and hydrocele of the round ligament. Some colored lithographs, presenting tolerable but not extraordinarily good illustrations of acute gonorrhœa with partial phimosis, balanoposthitis with herpetiform ulceration, paraphimosis with consequent ulceration, gonorrhœa in women, epididymitis, gonorrhœal conjunctivitis, and vulvo-vaginal abscess, accompany this article.

Mr. Howard Marsh's article on Abscesses is deserving of praise. As inflammation with, we presume, its sequelæ is to be treated of in another part of the *Cyclopædia*, it was not altogether an easy one to write, but Mr. March's arrangement of the subdivisions of his subject, and the mode in which he has treated them, leave nothing to be desired, and furnish a succinct and very instructive essay on the varieties, complications, terminations, and treatment of abscesses, enriched with many illustrations drawn from his own experience.

Venereal Diseases occupy, as they deserve to do, by far the largest section of the volume, and are considered under three heads, of which the first, embracing the simple Venereal Ulcer, or Chancroid, has been written by Dr. F. R. Sturgis, of New York; the second, including Syphilis, by Dr. Arthur van Harlingen; and the third, Venereal Diseases, including bubon d'émblée, warts, yaws, sarangi, sabbens, radesyge, and some other affections, by Dr. H. R. Wharton. Dr. Sturgis, whose experience has been very large, gives an interesting account of the gradual recognition by the professor of the two forms of venereal ulcer, now termed chancre and chancroid. He is himself an uncompromising dualist, and believes thoroughly, as we are inclined to do, in the specific distinction between soft and hard chancres, or rather between chancre and the initial lesion of syphilis. He gives the following characters as distinctive of the chancre and chancroid. An absence of any period of incubation, the sore usually appearing within the first eight days after the infecting coitus; the property of auto-inoculation; the absence of induration at the base; the copious purulent secretion; the punched-out and undermined edges of the sore; the eroded and irregular appearance of the floor; and, lastly, the greyish-yellow layer covering the floor. These symptoms must be taken collectively, for hardness of the base may be absent in the initial lesion of true syphilis, and other forms of pus when inoculated may produce sores. On the whole, he thinks it unnecessary to admit the existence of a specific virus in this form of ulcer, but considers that chancre is derived from the secretion of another chancre, or from a virulent (chancreoidal) bubo, and from nothing else.

The section on Syphilis, by Dr. Arthur van Harlingen, is not at all points in perfect accord with that on Chancroid. Dr. Sturgis seems in-

olined to give up the idea of the existence of a specific virus in chancre; whilst Dr. Harlingen holds fast to the doctrine of two kinds of venereal virus, the syphilitic and the chancreoid, and considers further that the two poisons can be inoculated simultaneously. He discusses the question of vaccino-syphilis, and, after giving the details of various outbreaks, observes that vaccino-syphilis may be derived from two sources, the vaccinifer and the vaccinated. The contagion is carried by means of the blood, and possibly by the epithelial scales and the white globules, and may infect either the vaccinifer or the vaccinated. He is satisfied that the initial lesion of syphilis is always a chancre, the average duration of incubation being forty-five days.

Transactions of the Clinical Society of London. Vol. XV. London: Longmans, Green & Co. 1882.

THIS is the most bulky volume of *Transactions* yet issued by this Society. It contains no less than forty-six papers and the reports of two committees. A glance through the titles of the papers published shows that they embrace a very wide field of clinical observation, and refer to most of the subjects in Clinical Medicine and Surgery that have recently excited special interest. There is a group of papers on Myxœdema, in which all our present knowledge on this obscure disease is to be found, and illustrated by the cases recorded. The recent advances in the surgical treatment of affections of the kidney are illustrated and discussed in no less than six communications, including accounts of the partial and complete removal of the organ for calculous or strumous disease and pyelitis, and of the removal of renal calculus in four cases. Dr. Greenhow continues the record of his results of the treatment of rheumatic fever in a paper on Cases Treated with Iodide of Potassium and Sulphate of Quinine. The volume contains an interesting report of a Committee on Chromidrosis, the most important part of which is the clear demonstration that while this affection is often simulated, it nevertheless does occur spontaneously and is a pathological verity. Following this is a long and careful report of a committee appointed to inquire into the Causes, Consequences, and Treatment of Hyperpyrexia in Rheumatic Fever and other Acute Febrile Diseases. The report contains some accurate observations and valuable facts, and although it does not throw light upon the causes or the pathological conditions in hyperpyrexia, it is a very valuable contribution to our clinical knowledge of this important complication of febrile disorders. The volume is sufficiently illustrated by woodcuts and chromolithograph plates, and is in all respects worthy of the Society.

An Atlas of Illustrations of Pathology. Compiled (chiefly from original sources) for the New Sydenham Society. Fasciculus IV. Diseases of the Liver. Plates XVII. to XXII., with Pathological Summary by Dr. GOODHART. London. 1882.

WHEN the Council of the New Sydenham Society decided upon the publication of a pathological atlas they not only took a step which decidedly increased the popularity of the Society, but gave an opportunity to English pathologists to declare the position they have attained. The present instalment is one of the best of the series yet issued. It comprises three colored plates—illustrations of brown atrophy, cirrhosis, tuberculosis and cystic disease of the liver, as well as lymphadenoma of

the spleen, and three other plates containing some fifty well-executed drawings of the pathological histology of the liver. The author's name is a sufficient guarantee of the good quality of the accompanying text, for Dr. Goodhart writes forcibly and clearly, and advances many well-considered arguments in support of his views, when these run counter to generally accepted statements. After introductory chapters upon the normal anatomy of the liver and its pathological changes in general, he discusses in turn each separate diseased condition. Perhaps the most interesting of these articles are those upon acute yellow atrophy and cirrhosis, as they are also the most elaborately discussed. Upon the question whether the former disease is primarily inflammatory or degenerative, Dr. Goodhart decides, after a thorough analysis, in favor of the latter view. Upon cirrhosis he speaks with much force in behalf of the identity of the process mainly as an interstitial inflammation in all the various forms of the disease, and will not admit the occurrence of a "biliary cirrhosis," with which the writings of Hanot, Charcot, and others have of late years familiarized us. The appearances of excessive bile-duct formation, which by some are attributed to proliferation of the hepatic cells, are explained by him as being merely concomitants of the main process, which is a spreading inflammation of Glisson's capsule; and his comparison of the so-called "hypertrophic cirrhosis" with malignant disease or tumour formation is worth reflection. This is not the place to attempt an adequate discussion of a subject that strikes at the very foundations of pathological processes, and of the part played by the secreting cells of a gland in its chronic tissue changes.

A Treatise on Human Physiology. By JOHN C. DALTON M.D. Seventh Edition, with 252 illustrations. London: J. Churchill. 1882.—This work presents a feature that is quite exceptional in our experience. It is a new edition of a well-known treatise on Physiology. It is well worked up to the present date; and yet it is not enlarged, but, on the contrary, is actually smaller than the last edition by 100 pages. This is in every respect highly creditable to Dr. Dalton's industry; for few are aware how difficult it is to intercalate new knowledge with old, or how a few words introduced at the commencement of a section involves the reconstruction, or at least rewording, of many subsequent paragraphs. In the volume before us, which has now reached its seventh edition, the last edition being published in 1876, the section devoted to physiological chemistry has been in great part rewritten, the characters of the albuminous compounds and of the ferments revealed by late researches being specially introduced. The arrangement of the proteid bodies into albumins, peptones, globulins, derived albumins, fibrin, coagulated proteids, and lardacein given by Gamgee, which is so convenient for teaching purposes, might, however, with advantage have been introduced. We notice, too, that nearly every page has received some touches, showing that it has been carefully revised, the reduction in size in the entire volume as compared with its predecessor being obtained not by leaving out points of essential importance, but by reducing statements previously given in a more diffused form. The account of the nervous system has been much enlarged and improved, and the book as it now stands may be regarded as a very good introduction to the study of physiology, and as supplying the student with all the information on this subject he need possess before entering upon the study of medicine.

A Compendium of Modern Pharmacy and Druggists' Formulary. By WALTER B. KILMER, Pharmaceutist. Fourth Edition. London: Henry Kemp-ton. 1882.—This work is intended primarily for chemists and druggists, but contains much useful and practical information which cannot fail to prove of interest to medical men. The tables alone would make it valuable as a work of reference. The formulæ have been carefully selected, many of them, although commonly used in America, being but little known in this country. For the preparation and compounding of elixirs alone there are over three hundred prescriptions. Some, it must be confessed, are most complex, and it would puzzle us to give an opinion as to the physiological action of the compounds they are intended to produce. For example, elixir of damiana contains, in addition to the fluid extract of that drug, hydrastis, nux vomica, orange-peel, cardamoms, glycerine, and hypophosphite of potash and soda. The compound elixir of tar seems to be a kind of universal cough medicine, and contains nearly twenty ingredients, including pure pine tar, pine sawdust, lobelia, Jamaica dog-wood, yerba santa, Hoffman's anodyne, oil of anise, sassafras, oil of peppermint, tartar emetic, and muriate of ammonia. The extract of jaborandi has a composition almost equally complex. The simple and compound extracts of cascara sagrada are by no means bad preparations, and will probably be found useful in cases of obstinate constipation. The compound elixir of chloroform may be regarded as a pleasant substitute for chlorodyne. Much of the information respecting flavoring and coloring, although curious and interesting, is of value only to those actually engaged in dispensing. The chapter on Specific Medicine is practical, but the author, in the absence of a medical education, blunders frequently in the use of technical terms. Such a word as "peritonitis" is not familiar to English readers. There are chapters replete with information on Emulsions, Medicated Wines, Pills, Perfumes, Pomades, Syrups, Toilet Waters, and other subjects of more or less interest to chemists. On the whole the work has been well done, and the information it contains is fairly accurate.

Mittheilungen aus der Ophthalmiatischen Klinik in Tübingen. Herausgegeben von Dr. ALBRECHT NAGEL. 3 Heft. 1882.—This part contains three articles: one by Schleich on Myopia, a second by Weiss on the Anatomy of the Myopic Eye, and the last by Professor Nagel himself on the Clinic of the Tübingen Eye Hospital. The article by Schleich is an important one, and gives the results of a large number of observations extended over many years in regard to the relation of myopia with sex, age, occupation, heredity, and other determining causes of the disease. The number of patients examined carefully, with a view to all these circumstances, has been 578, of whom 410 were males and 168 females, or 70.9 and 29.1 per cent. respectively, though the general proportion of all cases attending the hospital was 58.3 males and 41.7 females. The proportion of cases in regard to age was, up to ten years, 7 males, 3 females; from ten to twenty years, 137 males, 46 females; from twenty-one to thirty, 134 males, 35 females; from thirty-one to forty, 39 males, 25 females; from forty-one to fifty, 40 males, 21 females; from fifty-one to sixty, 26 males, 25 females; from sixty-one to seventy, 24 males, 10 females; over seventy, 3 males, 3 females. The average age was 30.9. The youngest was a boy of six. Though many infants were examined, not one case of myopia was observed in them. The numbers in relation to occupation were: teachers and those engaged in intel-

lectual pursuits, 43; official, 46; merchants, 33; students, 164; artisans and peasants, 124; women of position, 61; countrywomen, 76; maidservants, 20; schoolgirls, 11. Of the whole number of myops forty-seven were myopic on one side only. The lower grades of myopia, requiring three, four, five, and six dioptries for correcting glasses, were much the most common. The ophthalmoscopic appearances are given in some detail. Dr. Weiss gives at considerable length the anatomy of slight and of severe degrees of myopia.
